Heat-transfer and linear-elastic finite element analyses are used to determine the temperature field and stress field. The component reliability analysis module of CARES uses the thermoelastic or isothermal elastostatic results to calculate the time-independent reliability for each element using a specified reliability model. Each element can be made arbitrarily small, such that the stress field in an element can be approximated as constant throughout the element (or subelement). The algorithm is compatible with most (but not all) two-dimensional elements, three-dimensional elements, axisymmetric

elements, and shell elements for the commercial finite element algorithms mentioned above. Reliability calculations are performed at the Gaussian integration points of the element or, optionally, at the element centroid. Using the element integration points enables the element to be divided into subelements, where integration point subvolumes, subareas, and subtemperatures are calculated. The location of the Gaussian integration point in the finite element and the corresponding weight functions are considered when the subelement volume and/or area is calculated. The number of subelements in each element depends on the integration order chosen and the element type. If the probability of survival for each element is assumed to be a mutually exclusive event, the overall component reliability is the product of all the calculated element (or subelement) survival probabilities. The CARES algorithm produces an optional PATRAN file containing risk-of-rupture intensities (a local measure of reliability) for graphical rendering of the critical regions of the structure.

ERICA Algorithm. Unlike CARES, the AlliedSignal algorithm ERICA has a software architecture with a single module. Currently, only one finite element program interface exists for the algorithm, that is, an interface with the ANSYS finite element program. Once again stress and temperature information from the solution of a discretized component are used in conjunction with a specified reliability model to assess component reliability. ERICA admits multiple flaw distributions that can be spatially distributed through the volume, along the surface, and along the edges of a component. Both isotropic material behavior, and to a limited extent, anisotropic material behavior (for surface calculations) are taken into account. This anisotropic surface option allows the user to account for various types of surface finish on a component (e.g., ground, as fired, etc.). The ERICA algorithm can function on any platform that supports ANSYS. A limited number of element types are supported that offer the user some flexibility in modeling a component. Note that neither CARES nor ERICA support a full suite of elements for any of the commercial finite element algorithms.

Time-Independent Design Examples

Reliability analyses are typically segregated into two categories: time-independent and time-dependent. This classification is rooted both in the historic development of the reliability models presented here and also in a practical approach to the analysis of a component. Yet in many instances, a component must perform in an adequate fashion over a predetermined service life. To accomplish this design goal, the component must survive the initial load cycle. Thus, the calculated time-independent reliability value is used as a screening criterion and can also be used as an initial value for the time-dependent analyses discussed later. A fundamental premise of probabilistic analysis dictates that if the reliability of a component varies with time then it should never exceed the initial value (unless there exists some physical mechanism such as flaw healing that can account for this phenomenon). Typically, materials deteriorate with time, and this assumption is incorporated throughout this chapter. From historical perspective, the authors simply point out that the time-independent models were developed first (hence they are presented first here). In addition, the time-independent approach has been rigorously exercised over the years. Extensive design experience and databases have been established prior to proposal of the time-dependent modeling efforts outlined later in this chapter.

Both the CARES and ERICA reliability algorithms have been used in the design and analysis of numerous structural components. Of the two, the NASA CARES algorithm has been more widely utilized for proprietary reasons. The CARES reliability algorithm has been used to design glass and ceramic parts for a wide range of applications. These include hot section components for turbine and internal combustion engines, bearings, laser windows on test rigs, radomes, radiant heater tubes, spacecraft activation valves and platforms, CRTs, rocket launcher tubes, and ceramic packaging for microprocessors. Illustrated below are some typical design and analysis applications that have utilized the CARES software. In the interest of brevity, a complete example problem cannot be included in this article. For a complete step-by-step procedure on conducting a time-independent component reliability analysis, the reader is directed to Ref 12.

The CARES algorithm has been successfully used in the development of ceramic turbocharger wheels (Ref 41). Specifically, the CARES algorithm was utilized to design the CTV7301 silicon nitride turbocharger rotor, depicted in Fig. 5, which was implemented in the Caterpillar 3406E diesel engine. The reduced rotational inertia of the silicon nitride ceramic rotor compared to a metallic rotor significantly enhanced the turbocharger transient performance and reduced emissions. Note that this was a joint effort involving AlliedSignal and Caterpillar and represents the first design and large-scale deployment of ceramic turbochargers in the United States. More than 1700 units have been supplied to Caterpillar Tractor Company for on-highway truck engines. These units together have accumulated a total of over 120 million miles of service.

Extensive work has been performed to analyze graphite and ceramic structural components such as high-temperature valves, test fixtures, and turbine wheels using CARES. A silicon nitride turbine wheel has been designed as a retrofit to replace components fabricated from Waspaloy in a military cartridge-mode air turbine starter (Ref 42). The silicon nitride component reduced cost and weight while increasing resistance to temperature, erosion, and corrosion.

The CARES algorithm has been used to analyze a ceramic-to-metal brazed joint for automotive gas turbine engines (Ref 43, 44). A major design hurdle in ceramic-to-metal joining is the thermal expansion mismatch between the two different materials. This results in high residual stresses that increase the likelihood of ceramic failure. One of the goals of this work was to improve the capability of the metal shaft to transmit power by reducing concentrated tensile stresses. The results confirmed the importance of probabilistic failure analysis for assessing the performance of various brazed joint designs.

A monolithic graphite spacecraft activation valve was designed (Ref 45) to direct reaction control gases for fine tuning the trajectory of a high-performance kinetic energy kill vehicle during the last 9 s of flight. Utilizing the CARES software, the valve was designed to withstand a gas pressure of 11.4 MPa (1.6 ksi) at 1930 °C (3506 °F).

A design study (Ref 46) demonstrated the viability of an uncooled silicon nitride combustor for commercial application in a 300 kW engine with a turbine inlet temperature of 1370 °C (2498 °F). Using the CARES algorithm, an analysis identified the most severe transient thermal stress in an emergency shutdown. The most critical area was found to be around the dilution port.

Ceramic poppet valves for spark ignition engines have been designed (Ref 47). These parts, depicted with other engine components in Fig. 6, have been field tested in passenger cars with excellent results. Potential advantages offered by these valves include reduced seat insert and valve guide wear, improved valve train dynamics, increased engine output, and reduced friction loss using lower spring loads.

The largest known zinc-selenide (ZnSe) containment window (depicted in Fig. 7) was designed using the CARES algorithm. The window formed a pressure barrier between a cryogenic vacuum chamber containing optical equipment and a sensor chamber. The window measured 79 cm (31 in.) in diameter by 2.5 cm (1 in.) thick and was used in a test facility for long-range infrared sensors.

The previous examples cited successful applications of the reliability algorithms in the design and analysis of commercial applications. In many cases, the algorithms have been an integral component of research and development efforts in government-supported programs. A specific example of this is the use of the CARES algorithm by participating organizations in the Advanced Turbine Technology Applications Program (ATTAP) to determine the reliability of structural component designs. The ATTAP program (Ref 48) is intended to advance the technological readiness of the ceramic automotive gas turbine engine. Structural ceramic components represent the greatest technical challenge facing the commercialization of such an engine and are thus the prime project focus. Cooperative efforts have been developed between industry, key national facilities, and academia to capitalize on the unique capabilities and facilities developed for ceramic materials characterization and processing technology. Figure 8 depicts engine components, including structural, combustion, regeneration, and insulation applications designed using the NASA-developed CARES software.

Design with Brittle Materials

Stephen F. Duffy, Cleveland State University; Lesley A. Janosik, NASA Lewis Research Center

Life Prediction Using Reliability Analyses

The discussions in the previous sections assumed all failures were independent of time and history of previous thermomechanical loadings. However, as design protocols emerge for brittle material systems, designers must be aware of several innate characteristics exhibited by these materials. When subjected to elevated service temperatures, they exhibit complex thermomechanical behavior that is both inherently time dependent and hereditary in the sense that current behavior depends not only on current conditions, but also on thermomechanical history. The design engineer must also be cognizant that the ability of a component to sustain load degrades over time due to a variety of effects such as oxidation, creep, stress corrosion, and cyclic fatigue. Stress corrosion and cyclic fatigue result in a phenomenon called subcritical crack growth (SCG). This failure mechanism initiates at a preexisting flaw and continues until a critical length is attained. At that point, the crack grows in an unstable fashion leading to catastrophic failure. The SCG failure mechanism is a time-dependent, load-induced phenomenon. Time-dependent crack growth can also be a function of chemical reaction, environment, debris wedging near the crack tip, and deterioration of bridging ligaments. Fracture mechanism maps, such as the one developed for ceramic materials (Ref 49) depicted in Fig. 9, help illustrate the relative contribution of various failure modes as a function of temperature and stress.

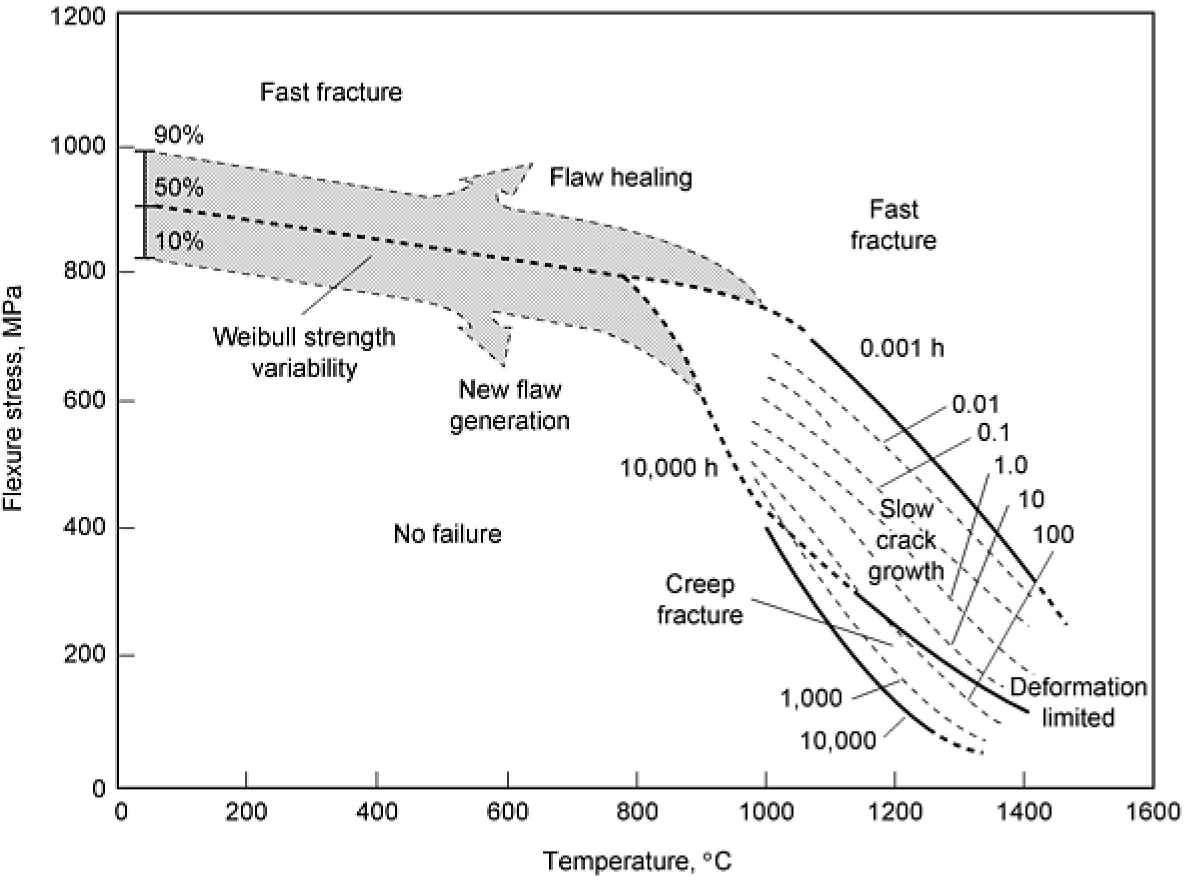

Fig. 9 Fracture mechanism map for hot-pressed silicon nitride flexure bars. Fracture mechanism maps help illustrate the relative contribution of various failure modes as a function of temperature and stress. Source: Ref 49

In addition to the determination of the Weibull shape and scale parameters discussed previously, analysis of time-dependent reliability in brittle materials necessitates accurate stress field information, as well as evaluation of distinct parameters reflecting material, microstructural, and/or environmental conditions. Predicted lifetime reliability of brittle material components depends on Weibull and fatigue parameters estimated from rupture data obtained from widely used tests involving flexural or tensile specimens. Fatigue parameter estimates are obtained from naturally flawed specimens ruptured under static (creep), cyclic, or dynamic (constant stress rate) loading. For other specimen geometries, a finite element model of the specimen is also required when estimating these parameters. For a more detailed discussion of time-dependent parameter estimation, the reader is directed to the *CARES/Life (CARES/Life Prediction Program) Users and Programmers Manual* (Ref 50). This information can then be combined with stochastic modeling approaches and incorporated into integrated design algorithms (computer software) in a manner similar to that presented previously for time-independent models. The theoretical concepts upon which these time-dependent algorithms have been constructed and the effects of time-dependent mechanisms, most notably subcritical crack growth and creep, are addressed in the remaining sections of this article.

Although it is not discussed in detail here, one approach to improve the confidence in component reliability predictions is to subject the component to proof testing prior to placing it in service. Ideally, the boundary conditions applied to a component under proof testing simulate those conditions the component would be subjected to in service, and the proof test loads are appropriately greater in magnitude over a fixed time interval. This form of testing eliminates the weakest components and, thus, truncates the tail of the strength distribution curve. After proof testing, surviving components can be placed in service with greater confidence in their integrity and a predictable minimum service life.

Need for Correct Stress State

With increasing use of brittle materials in high-temperature structural applications, the need arises to accurately predict thermomechanical behavior. Most current analytical methods for both subcritical crack growth and creep models use elastic stress fields in predicting the time-dependent reliability response of components subjected to elevated service temperatures. Inelastic response at high temperature has been well documented in the materials science literature for these material systems, but this issue has been ignored by the engineering design community. However, the authors wish to emphasize that accurate predictions of time-dependent reliability demand accurate stress-field information. From a design engineer's perspective, it is imperative that the inaccuracies of making time-dependent reliability predictions based on elastic stress fields are taken into consideration. This section addresses this issue by presenting a recent formulation of a viscoplastic constitutive theory to model the inelastic deformation behavior of brittle materials at high temperatures.

Early work in the field of metal plasticity indicated that inelastic deformations are essentially unaffected by hydrostatic stress. This is not the case for brittle (e.g., ceramic-based) material systems, unless the material is fully dense. The theory presented here allows for fully dense material behavior as a limiting case. In addition, as pointed out in Ref 51, these materials exhibit different time-dependent behavior in tension and compression. Thus, inelastic deformation models for these materials must be constructed in a manner that admits sensitivity to hydrostatic stress and differing behavior in tension and compression.

A number of constitutive theories for materials that exhibit sensitivity to the hydrostatic component of stress have been proposed that characterize deformation using time-independent classical plasticity as a foundation. Corapcioglu and Uz (Ref 52) reviewed several of these theories by focusing on the proposed form of the individual yield function. The review includes the works of Kuhn and Downey (Ref 53), Shima and Oyane (Ref 54), and Green (Ref 55). Not included is the work by Gurson (Ref 56), who not only developed a yield criteria and flow rule, but also discussed the role of void nucleation. Subsequent work by Mear and Hutchinson (Ref 57) extended Gurson's work to include kinematic hardening of the yield surfaces.

Although the previously mentioned theories admit a dependence on the hydrostatic component of stress, none of these theories allows different behavior in tension and compression. In addition, the aforementioned theories are somewhat lacking in that they are unable to capture creep, relaxation, and rate-sensitive phenomena exhibited by brittle materials at high temperature. Noted exceptions are the recent work by Ding et al. (Ref 58) and the work by White and Hazime (Ref 59). Another exception is an article by Liu et al. (Ref 60), which is an extension of the work presented by Ding and

coworkers. As these authors point out, when subjected to elevated service temperatures, brittle materials exhibit complex thermomechanical behavior that is inherently time dependent and hereditary in the sense that current behavior depends not only on current conditions, but also on thermomechanical history.

The macroscopic continuum theory formulated in the remainder of this section captures these time-dependent phenomena by developing an extension of a J_2 plasticity model first proposed by Robinson (Ref 61) and later extended to sintered powder metals by Duffy (Ref 62). Although the viscoplastic model presented by Duffy (Ref 62) admitted a sensitivity to hydrostatic stress, it did not allow for different material behavior in tension and compression.

Willam and Warnke (Ref 63) proposed a yield criterion for concrete that admits a dependence on the hydrostatic component of stress and explicitly allows different material responses in tension and compression. Several formulations of their model exist, that is, a three-parameter formulation and a five-parameter formulation. For simplicity, the overview of the multiaxial derivation of the viscoplastic constitutive model presented here builds on the three-parameter formulation. The attending geometrical implications have been presented elsewhere (Ref 64, 65). A quantitative assessment has yet to be conducted because the material constants have not been suitably characterized for a specific material. The quantitative assessment could easily dovetail with the nascent efforts of White and coworkers (Ref 59).

The complete theory is derivable from a scalar dissipative potential function identified here as Ω. Under isothermal conditions, this function is dependent on the applied stress σ_{ij} and internal state variable α_{ij}:

$$\Omega = \Omega(\sigma_{ij}, \alpha_{ij}) \qquad \textbf{(Eq 53)}$$

The stress dependence for a J_2 plasticity model or a J_2 viscoplasticity model is usually stipulated in terms of the deviatoric components of the applied stress, $S_{ij} = \sigma_{ij} - \left(\frac{1}{3}\right) \sigma_{kk}\delta_{ij}$, and a deviatoric state variable, $a_{ij} = \alpha_{ij} - \left(\frac{1}{3}\right) \alpha_{kk}\delta_{ij}$. For the viscoplasticity model presented here, these deviatoric tensors are incorporated along with the effective stress, $\eta_{ij} = \sigma_{ij} - \alpha_{ij}$, and an effective deviatoric stress, identified as $\Sigma_{ij} = S_{ij} - a_{ij}$. Both tensors, that is, η_{ij} and Σ_{ij}, are utilized for notational convenience.

The potential nature of Ω is exhibited by the manner in which the flow and evolutionary laws are derived. The flow law is derived from Ω by taking the partial derivative with respect to the applied stress:

$$\dot{\varepsilon}_{ij} = \frac{\partial \Omega}{\partial \sigma_{ij}} \qquad \textbf{(Eq 54)}$$

The adoption of a flow potential and the concept of normality, as expressed in Eq 54, were introduced by Rice (Ref 66). In his work, the above relationship was established using thermodynamic arguments. The authors wish to point out that Eq 54 holds for each individual inelastic state.

The evolutionary law is similarly derived from the flow potential. The rate of change of the internal stress is expressed as:

$$\dot{\alpha}_{ij} = -h \frac{\partial \Omega}{\partial \alpha_{ij}} \qquad \textbf{(Eq 55)}$$

where h is a scalar function of the inelastic state variable (i.e., the internal stress) only. Using arguments similar to Rice's, Ponter, and Leckie (Ref 67) have demonstrated the appropriateness of this type of evolutionary law.

To give the flow potential a specific form, the following integral format proposed by Robinson (Ref 61) is adopted:

$$\Omega = K^2 \left[\left(\frac{1}{2\mu}\right) \int F^n \, dF + \left(\frac{R}{H}\right) \int G^m \, dG \right] \qquad \textbf{(Eq 56)}$$

where μ, R, H, and K are material constants. In this formulation μ is a viscosity constant, H is a hardening constant, n and m are unitless exponents, and R is associated with recovery. The octahedral threshold shear stress K appearing in Eq 56 is generally considered a scalar state variable that accounts for isotropic hardening (or softening). However, because isotropic hardening is often negligible at high homologous temperatures ($T/T_m \geq 0.5$), to a first approximation K is taken to be a constant for metals. This assumption is adopted in the present work for brittle materials. The reader is directed to Ref 68 for specific details regarding the experimental test matrix needed to characterize these parameters.

The dependence on the effective stress Σ_{ij} and the deviatoric internal stress a_{ij} is introduced through the scalar functions $F = F(\Sigma_{ij}, \eta_{ij})$ and $G = G(a_{ij}, \alpha_{ij})$. Inclusion of η_{ij} and α_{ij} will account for sensitivity to hydrostatic stress. The concept of a threshold function was introduced by Bingham (Ref 69) and later generalized by Hohenemser and Prager (Ref 70). Correspondingly, F is referred to as a Bingham-Prager threshold function. Inelastic deformation occurs only for those stress states where $F(\Sigma_{ij}, \eta_{ij}) > 0$.

For frame indifference, the scalar functions F and G (and hence Ω) must be form invariant under all proper orthogonal transformations. This condition is ensured if the functions depend only on the principal invariants of Σ_{ij}, a_{ij} η_{ij}, and α_{ij}; that is, $F = F(\tilde{I}_1, \tilde{J}_2, \tilde{J}_3)$, where $\tilde{I}_1 = \eta_{ii}$, $\tilde{J}_2 = (\frac{1}{2})\Sigma_{ij}\Sigma_{ij}$, $\tilde{J}_3 = (\frac{1}{3})\Sigma_{ij}\Sigma_{jk}\Sigma_{ki}$, and $G = G(\hat{I}_1, \hat{J}_2, \hat{J}_3)$, where $I_1 = a_{ii}$, $J_2 = (\frac{1}{2})a_{ij}a_{ij}$, $J_3 = (\frac{1}{3})a_{ij}a_{jk}a_{ki}$. These scalar quantities are elements of what is known in invariant theory as an integrity basis for the functions F and G.

A three-parameter flow criterion proposed by Willam and Warnke (Ref 63) serves as the Bingham-Prager threshold function, F. The William-Warnke criterion uses the previously mentioned stress invariants to define the functional dependence on the Cauchy stress (σ_{ij}) and internal state variable (α_{ij}). In general, this flow criterion can be constructed from the following general polynomial:

$$F = \lambda\left(\frac{\sqrt{\tilde{J}_2}}{\sigma_c}\right) + B\left(\frac{\tilde{I}_1}{\sigma_c}\right) - 1 \qquad \textbf{(Eq 57)}$$

where σ_c is the uniaxial threshold flow stress in compression and B is a constant determined by considering homogeneously stressed elements in the virgin inelastic state $\alpha_{ij} = 0$.

Note that a threshold flow stress is similar in nature to a yield stress in classical plasticity. In addition, λ is a function dependent on the invariant J_3 and other threshold stress parameters that are defined momentarily. The specific details in deriving the final form of the function F can be found in Willam and Warnke (Ref 63), and this final formulation is stated here as:

$$F(\tilde{I}_1, \tilde{J}_2, \tilde{J}_3) = \frac{1}{\sigma_c}\left[\frac{1}{r(\tilde{\theta})}\right]\left[\frac{2\tilde{J}_2}{5}\right]^{1/2} + \frac{\tilde{I}_1}{3\rho\sigma_c} - 1 \qquad \textbf{(Eq 58)}$$

for brevity. The invariant $\tilde{I}_1$ in Eq 58 admits a sensitivity to hydrostatic stress. The function F is implicitly dependent on $\tilde{J}_3$ through the function $r(\tilde{\theta})$, where the angle of similitude, $\tilde{\theta}$, is defined by the expression:

$$\cos(3\tilde{\theta}) = \frac{(3\sqrt{3})\tilde{J}_3}{2(\tilde{J}_2)^{3/2}} \qquad \textbf{(Eq 59)}$$

The invariant $\tilde{J}_3$ accounts for different behavior in tension and compression, because this invariant changes sign when the direction of a stress component is reversed. The parameter ρ characterizes the tensile hydrostatic threshold flow stress. For the Willam-Warnke three-parameter formulation, the model parameters include σ_t, the tensile uniaxial threshold stress, σ_c, the compressive uniaxial threshold stress, and σ_{bc}, the equal biaxial compressive threshold stress.

A similar functional form is adopted for the scalar state function *G*. However, this formulation assumes a threshold does not exist for the scalar function *G* and follows the framework of previously proposed constitutive models based on Robinson's viscoplastic law (Ref 61).

Employing the chain rule for differentiation and evaluating the partial derivative of Ω with respect to σ_{ij}, and then with respect to α_{ij}, as indicated in Eq 54 and 55, yields the flow law and the evolutionary law, respectively. These expressions are dependent on the principal invariants (i.e., $\tilde{I}_1$, $\tilde{J}_2$, $\tilde{J}_3$, $\hat{I}_1$, $\hat{J}_2$, and $\hat{J}_3$) the three Willam-Warnke threshold parameters (i.e., σ_t, σ_c, and σ_{bc}), and the flow potential parameters utilized in Eq 56 (i.e., μ, *R*, *H*, *K*, *n*, and *m*). These expressions constitute a multiaxial statement of a constitutive theory for isotropic materials and serve as an inelastic deformation model for ceramic materials.

The overview presented in this section is intended to provide a qualitative assessment of the capabilities of this viscoplastic model in capturing the complex thermomechanical behavior exhibited by brittle materials at elevated service temperatures. Constitutive equations for the flow law (strain rate) and evolutionary law have been formulated based on a threshold function that exhibits a sensitivity to hydrostatic stress and allows different behavior in tension and compression. Furthermore, inelastic deformation is treated as inherently time dependent. A rate of inelastic strain is associated with every state of stress. As a result, creep, stress relaxation, and rate sensitivity are phenomena resulting from applied boundary conditions and are not treated separately in an ad hoc fashion. Incorporating this model into a nonlinear finite element code would provide a tool for the design engineer to simulate numerically the inherently time-dependent and hereditary phenomena exhibited by these materials in service.

Life Prediction Reliability Models

Using a time-dependent reliability model such as those discussed in the following section, and the results obtained from a finite element analysis, the life of a component with complex geometry and loading can be predicted. This life is interpreted as the reliability of a component as a function of time. When the component reliability falls below a predetermined value, the associated point in time at which this occurs is assigned the life of the component. This design methodology presented herein combines the statistical nature of strength-controlling flaws with the mechanics of crack growth to allow for multiaxial stress states, concurrent (simultaneously occurring) flaw populations, and scaling effects. With this type of integrated design tool, a design engineer can make appropriate design changes until an acceptable time to failure has been reached. In the sections that follow, only creep rupture and fatigue failure mechanisms are discussed. Although models that account for subcritical crack growth and creep rupture are presented, the reader is cautioned that currently available creep models for advanced ceramics have limited applicability because of the phenomenological nature of the models. There is a considerable need to develop models incorporating both the ceramic material behavior and microstructural events.

Subcritical Crack Growth. A wide variety of brittle materials, including ceramics and glasses, exhibit the phenomenon of delayed fracture or fatigue. Under the application of a loading function of magnitude smaller than that which induces short-term failure, there is a regime where subcritical crack growth occurs and this can lead to eventual component failure in service. Subcritical crack growth is a complex process involving a combination of simultaneous and synergistic failure mechanisms. These can be grouped into two categories: (1) crack growth due to corrosion and (2) crack growth due to mechanical effects arising from cyclic loading. Stress corrosion reflects a stress-dependent chemical interaction between the material and its environment.Water, for example, has a pronounced deleterious effect on the strength of glass and alumina. In addition, higher temperatures also tend to accelerate this process. Mechanically induced cyclic fatigue is dependent only on the number of load cycles and not on the duration of the cycle. This phenomenon can be caused by a variety of effects, such as debris wedging or the degradation of bridging ligaments, but essentially it is based on the accumulation of some type of irreversible damage that tends to enhance crack growth. Service environment, material composition, and material microstructure determine if a brittle material will display some combination of these fatigue mechanisms.

Lifetime reliability analysis accounting for SCG under cyclic and/or sustained loads is essential for the safe and efficient utilization of brittle materials in structural design. Because of the complex nature of SCG, models that have been developed tend to be semiempirical and approximate the behavior of SCG phenomenologically. Theoretical and experimental work in this area has demonstrated that lifetime failure characteristics can be described by consideration of the crack growth rate versus the stress intensity factor (or the range in the stress intensity factor). This is graphically depicted (see Fig. 10) as the logarithm of crack growth rate versus the logarithm of the mode I stress intensity factor. Curves of experimental data show three distinct regimes or regions of growth. The first region (denoted by I in Fig. 10) indicates threshold behavior of the crack, where below a certain value of stress intensity the crack growth is zero. The

second region (denoted by II in Fig. 10) shows an approximately linear relationship of stable crack growth.The third region (denoted by III in Fig. 10) indicates unstable crack growth as the materials critical stress intensity factor is approached. For the stress-corrosion failure mechanism, these curves are material and environment sensitive. This SCG model, using conventional fracture mechanics relationships, satisfactorily describes the failure mechanisms in materials where at high temperatures, plastic deformations and creep behave in a linear viscoelastic manner (Ref 71). In general, at high temperatures and low levels of stress, failure is best described by creep rupture, which generates new cracks (Ref 72). The creep rupture process is discussed further in the next section.

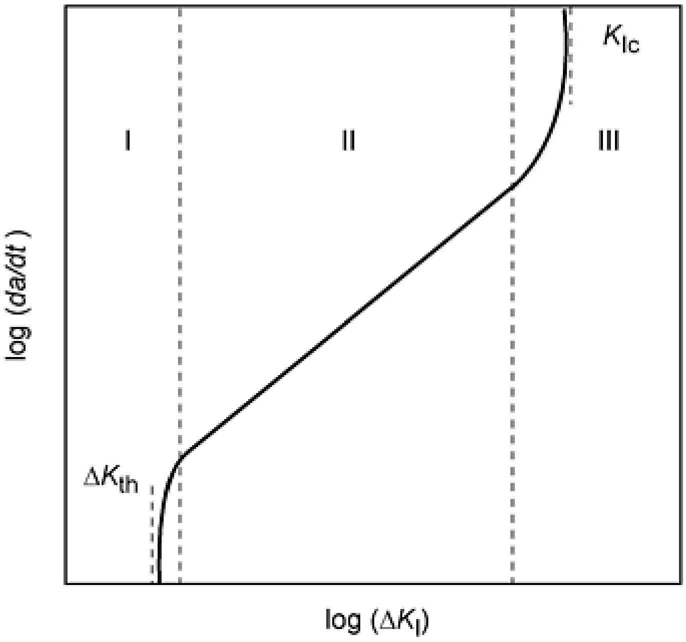

Fig. 10 Schematic illustrating three different regimes of crack growth

The most-often-cited models in the literature regarding SCG are based on power-law formulations.Other theories, most notably Wiederhorn's (Ref 73), have not achieved such widespread usage, although they may also have a reasonable physical foundation. Power-law formulations are used to model both the stress-corrosion phenomenon and the cyclic fatigue phenomenon.This modeling flexibility, coupled with their widespread acceptance, make these formulations the most attractive candidates to incorporate into a design methodology. A power-law formulation is obtained by assuming the second crack growth region is linear and that it dominates the other regions. Three power-law formulations are useful for modeling brittle materials: the power law, the Paris law, and the Walker equation. The power law (Ref 71, 74) describes the crack velocity as a function of the stress intensity factor and implies that the crack growth is due to stress corrosion. For cyclic fatigue, either the Paris law (Ref 75) or Walker's (Ref 76, 77) modified formulation of the Paris law is used to model the SCG. The Paris law describes the crack growth per load cycle as a function of the range in the stress intensity factor. The Walker equation relates the crack growth per load cycle to both the range in the crack tip stress intensity factor and the maximum applied crack tip stress intensity factor. It is useful for predicting the effect of the *R*-ratio (the ratio of the minimum cyclic stress to the maximum cyclic stress) on the material strength degradation.

Expressions for time-dependent reliability are usually formulated based on the mode I equivalent stress distribution transformed to its equivalent stress distribution at time t = 0. Investigations of mode I crack extension (Ref 78) have resulted in the following relationship for the equivalent mode I stress intensity factor:

$$K_{Ieq} (\Psi, t) = \sigma_{Ieq} (\Psi, t)\, Y \sqrt{a(\psi,t)} \quad \textbf{(Eq 60)}$$

where σ_{Ieq} (Ψ, t) is the equivalent mode I stress on the crack, Y is a function of crack geometry, a (Ψ, t) is the appropriate crack length, and Ψ represents a spatial location within the body and the orientation of the crack. In some models (such as the phenomenological Weibull NSA and the PIA models), Ψ represents a location only. Y is a function of

crack geometry; however, herein it is assumed constant with subcritical crack growth. Crack growth as a function of the equivalent mode I stress intensity factor is assumed to follow a power-law relationship:

$$\frac{da\,(\Psi, t)}{dt} = A\,K_{\mathrm{Ieq}}^{N}\,(\Psi, t) \qquad \textbf{(Eq 61)}$$

where A and N are material/environmental constants.The transformation of the equivalent stress distribution at the time of failure, $t = t_f$, to its critical effective stress distribution at time $t = 0$ is expressed (Ref 79, 80):

$$\sigma_{\mathrm{Ieq},0}\,(\Psi, t_f) = \left[\frac{\int_0^{t_f} \sigma_{\mathrm{Ieq}}^{N}\,(\Psi, t)\,dt}{B} + \sigma_{\mathrm{Ieq}}^{N-2}\,(\Psi, t_f) \right]^{1/(N-2)} \qquad \textbf{(Eq 62)}$$

where

$$B = \frac{2}{A\,Y^2\,K_{\mathrm{Ic}}^{N-2}\,(N-2)} \qquad \textbf{(Eq 63)}$$

is a material/environmental fatigue parameter, K_{Ic} is the critical stress intensity factor, and $\sigma_{\mathrm{Ieq}}\,(\Psi, t_f)$ is the equivalent stress distribution in the component at time $t = t_f$. The dimensionless fatigue parameter N is independent of fracture criterion. B is adjusted to satisfy the requirement that for a uniaxial stress state, all models produce the same probability of failure. The parameter B has units of stress^2 × time.

Because SCG assumes flaws exist in a material, the weakest-link statistical theories discussed previously are required to predict the time-dependent lifetime reliability for brittle materials. An SCG model (e.g., the previously discussed power law, Paris law, or Walker equation) is combined with either the two- or three-parameter Weibull cumulative distribution function to characterize the component failure probability as a function of service lifetime. The effects of multiaxial stresses are considered by using the PIA model, the Weibull NSA method, or the Batdorf theory. These multiaxial reliability expressions were outlined in the previous section on time-independent reliability analysis models, and, for brevity, are not repeated here. The reader is directed to see the previous section or, for more complete details, to consult Ref 50.

Creep Rupture. For brittle materials, the term creep can infer two different issues. The first relates to catastrophic failure of a component from a defect that has been nucleated and propagates to critical size. This is known as creep rupture to the design engineer. Here, it is assumed that failure does not occur from a defect in the original flaw population. Unlike SCG, which is assumed to begin at preexisting flaws in a component and continue until the crack reaches a critical length, creep rupture typically entails the nucleation, growth, and coalescence of voids which eventually form macrocracks, which then propagate to failure. The second issue related to creep reflects back on SCG as well as creep rupture, that is, creep deformation. This section focuses on the former, while the latter (i.e., creep deformation) is discussed in a previous section.

Currently, most approaches to predict brittle material component lifetime due to creep rupture employ deterministic methodologies. Stochastic methodologies for predicting creep life in brittle material components have not reached a level of maturity comparable to those developed for predicting fast-fracture and SCG reliability. One such theory is based on the premise that both creep and SCG failure modes act simultaneously (Ref 81). Another alternative method for characterizing creep rupture in ceramics was developed by Duffy and Gyekenyesi, (Ref 82), who developed a time-dependent reliability model that integrates continuum damage mechanics principles and Weibull analysis. This particular approach assumes that the failure processes for SCG and creep are distinct and separable mechanisms.

The remainder of this section outlines this approach, highlighting creep rupture with the intent to provide the design engineer with a method to determine an allowable stress for a given component lifetime and reliability. This is accomplished by coupling Weibull theory with the principles of continuum damage mechanics, which was originally developed by Kachanov (Ref 83) to account for tertiary creep and creep fracture of ductile metal alloys.

Ideally, any theory that predicts the behavior of a material should incorporate parameters that are relevant to its microstructure (grain size, void spacing, etc.). However, this would require a determination of volume-averaged effects of microstructural phenomena reflecting nucleation, growth, and coalescence of microdefects that in many instances interact. This approach is difficult even under strongly simplifying assumptions. In this respect, Leckie (Ref 84) points out that the difference between the materials scientists and the engineer is one of scale. He notes the materials scientist is interested in mechanisms of deformation and failure at the microstructural level and the engineer focuses on these issues at the component level. Thus, the former designs the material and the latter designs the component. Here, the engineer's viewpoint is adopted, and readers should note from the outset that continuum damage mechanics does not focus attention on microstructural events, yet this logical first approach does provide a practical model, which macroscopically captures the changes induced by the evolution of voids and defects.

This method uses a continuum-damage approach where a continuity function, ϕ, is coupled with Weibull theory to render a time-dependent damage model for ceramic materials. The continuity function is given by the expression:

$$\phi = [1 - b(\sigma_0)^m(m + 1)t]^{(1/(m+1))} \quad \textbf{(Eq 64)}$$

where b and m are material constants, σ_0 is the applied uniaxial stress on a unit volume, and t is time. From this, an expression for a time to failure, t_f, can be obtained by noting that when $t = t_f$, $\phi = 0$. This results in the following:

$$t_f = \frac{1}{b\,(\sigma_0)^m\,(m + 1)} \quad \textbf{(Eq 65)}$$

which leads to the simplification of ϕ as follows:

$$\phi = [1 - (t/t_f)]^{(1/(m+1))} \quad \textbf{(Eq 66)}$$

The above equations are then coupled with an expression for reliability to develop the time-dependent model. The expression for reliability for a uniaxial specimen is:

$$R = \exp\,[\,-V\,(\sigma/\beta)^{\alpha}\,] \quad \textbf{(Eq 67)}$$

where V is the volume of the specimen, α is the Weibull shape parameter, and β is the Weibull scale parameter. Incorporating the continuity function into the reliability equation and assuming a unit volume yields:

$$R = \exp\,[\,-(\sigma_0/\phi\beta)^{\alpha}\,] \quad \textbf{(Eq 68)}$$

Substituting for ϕ in terms of the time to failure results in the time-dependent expression for reliability:

$$R = \exp\left\{-\left(\frac{\sigma_0}{\beta}\right)^{\alpha}\left[1 - \frac{t}{t_f}\right]^{-(\alpha/m+1)}\right\} \quad \textbf{(Eq 69)}$$

This model has been presented in a qualitative fashion, intending to provide the design engineer with a reliability theory that incorporates the expected lifetime of a brittle material component undergoing damage in the creep rupture regime. The predictive capability of this approach depends on how well the macroscopic state variable ϕ captures the growth of grain-boundary microdefects. Finally, note that the kinetics of damage also depend significantly on the direction of the applied stress. In the development described previously, it was expedient from a theoretical and computational standpoint to use a scalar state variable for damage because only uniaxial loading conditions were considered. The incorporation of a continuum-damage approach within a multiaxial Weibull analysis necessitates the description of oriented damage by a second-order tensor.

Life-Prediction Reliability Algorithms

The NASA-developed computer program CARES/*Life* (Ceramics Analysis and Reliability Evaluation of Structures/Life-Prediction program) and the AlliedSignal algorithm ERICA have the capability to evaluate the time-dependent reliability of monolithic ceramic components subjected to thermomechanical and/or proof test loading. The reader is directed to Ref 39 and Ref 40 for a detailed discussion of the life-prediction capabilities of the ERICA algorithm. The CARES/*Life* program is an extension of the previously discussed CARES program, which predicted the fast-fracture (time-independent) reliability of monolithic ceramic components. CARES/*Life* retains all of the fast-fracture capabilities of the CARES program and also includes the ability to perform time-dependent reliability analysis due to SCG. CARES/*Life* accounts for the phenomenon of SCG by utilizing the power law, Paris law, or Walker equation. The Weibull cumulative distribution function is used to characterize the variation in component strength. The probabilistic nature of material strength and the effects of multiaxial stresses are modeled using either the PIA, the Weibull NSA, or the Batdorf theory. Parameter estimation routines are available for obtaining inert strength and fatigue parameters from rupture strength data of naturally flawed specimens loaded in static, dynamic, or cyclic fatigue. Fatigue parameters can be calculated using either the median value technique (Ref 85), a least squares regression technique, or a median deviation regression method that is somewhat similar to trivariant regression (Ref 85). In addition, CARES/*Life* can predict the effect of proof testing on component service probability of failure. Creep and material healing mechanisms are not addressed in the CARES/*Life* code.

Life-Prediction Design Examples

Once again, because of the proprietary nature of the ERICA algorithm, the life-prediction examples presented in this section are all based on design applications where the NASA CARES/*Life* algorithm was utilized. Either algorithm should predict the same results cited here. However, at this point in time comparative studies utilizing both algorithms for the same analysis are not available in the open literature. The primary thrust behind CARES/*Life* is the support and development of advanced heat engines and related ceramics technology infrastructure. This U.S. Department of Energy (DOE), and Oak Ridge National Laboratory (ORNL) have several ongoing programs such as the Advanced Turbine Technology Applications Project (ATTAP) (Ref 48, 86) for automotive gas turbine development, the Heavy Duty Transport Program for low-heat-rejection heavy-duty diesel engine development, and the Ceramic Stationary Gas Turbine (CSGT) program for electric power cogeneration. Both CARES/*Life* and the previously discussed CARES program are used in these projects to design stationary and rotating equipment, including turbine rotors, vanes, scrolls, combustors, insulating rings, and seals. These programs are also integrated with the DOE/ORNL Ceramic Technology Project (CTP) (Ref 87) characterization and life prediction efforts (Ref 88, 89).

The CARES/*Life* program has been used to design hot-section turbine parts for the CSGT development program (Ref 90) sponsored by the DOE Office of Industrial Technology. This project seeks to replace metallic hot-section parts with uncooled ceramic components in an existing design for a natural-gas-fired industrial turbine engine operating at a turbine rotor inlet temperature of 1120 °C (2048 °F). At least one stage of blades (Fig. 11) and vanes, as well as the combustor liner, will be replaced with ceramic parts. Ultimately, demonstration of the technology will be proved with a 4000 h engine field test.

Ceramic pistons for a constant-speed drive are being developed. Constant-speed drives are used to convert variable engine speed to a constant output speed for aircraft electrical generators. The calculated probability of failure of the piston is less than 0.2×10^{-8} under the most severe limit-load condition. This program is sponsored by the U.S. Navy and ARPA (Advanced Research Projects Agency, formerly DARPA, Defense Advanced Research Projects Agency). As depicted in Fig. 12, ceramic components have been designed for a number of other applications, most notably for aircraft auxiliary power units.

Glass components behave in a similar manner as ceramics and must be designed using reliability evaluation techniques. The possibility of alkali strontium silicate glass CRTs spontaneously imploding has been analyzed (Ref 91). Cathode ray tubes are under a constant static load due to the pressure forces placed on the outside of the evacuated tube. A 68 cm (27 in.) diagonal tube was analyzed with and without an implosion protection band. The implosion protection band reduces the overall stresses in the tube and, in the event of an implosion, also contains the glass particles within the enclosure. Stress analysis (Fig. 13) showed compressive stresses on the front face and tensile stresses on the sides of the tube. The implosion band reduced the maximum principal stress by 20%. Reliability analysis with CARES/*Life* showed that the implosion protection band significantly reduced the probability of failure to about 5×10^{-5}.

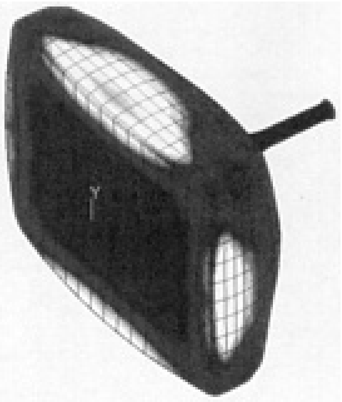

Fig. 13 Stress plot of an evacuated 68 cm (27 in.) diagonal CRT. The probability of failure calculated with CARES/Life was less than 5.0×10^{-3}. Courtesy of Philips Display Components Company

The structural integrity of a silicon carbide convection air heater for use in an advanced power-generation system has been assessed by ORNL and the NASA Lewis Research Center. The design used a finned tube arrangement 1.8 m (70.9 in.) in length with 2.5 cm (1 in.) diam tubes. Incoming air was to be heated from 390 to 700 °C (734 to 1292 °F). The hot

gas flow across the tubes was at 980 °C (1796 °F). Heat transfer and stress analyses revealed that maximum stress gradients across the tube wall nearest the incoming air would be the most likely source of failure.

Probabilistic design techniques are being applied to dental ceramic crowns, as illustrated in Fig. 14. Frequent failure of some ceramic crowns (e.g., 35% failure of molar crowns after three years), which occurs because of residual and functional stresses, necessitates design modifications and improvement of these restorations. Thermal tempering treatment is being investigated as a means of introducing compressive stresses on the surface of dental ceramics to improve the resistance to failure (Ref 92). Evaluation of the risk of material failure must be considered not only for the service environment, but also from the tempering process.

Design with Plastics

G.G. Trantina, General Electric Corporate Research and Development

Introduction

THE KEY to any successful part development is the proper choice of material, process, and design matched to the part performance requirements. The ability to design plastic parts requires knowledge of material properties--performance indicators that are not design or geometry dependent--rather than material comparators that apply only to a specific geometry and loading. Understanding the true effects of time, temperature, and rate of loading on material performance can make the difference between a successful application and catastrophic failure. Examples of reliable material performance indicators and common practices to avoid are presented in this article. Simple tools and techniques for predicting part performance (stiffness, strength/impact, creep/stress relaxation and fatigue) integrated with manufacturing concerns (flow length and cycle time) are demonstrated for design and material selection.

Engineering plastics are now used in applications where their mechanical performance must meet increasingly demanding requirements. Because the marketplace is more competitive, companies cannot afford overdesigned parts or lengthy, iterative product-development cycles. Therefore, engineers must have design technologies that allow them to create productively the most cost-effective design with the optimal material and process selection.

The design-engineering process involves meeting end-use requirements with the lowest cost, design, material, and process combination (Fig. 1). Design activities include creating geometries and performing engineering analysis to predict part performance. Material characterization provides engineering design data, and process selection includes process/design interaction knowledge. In general, the challenge in designing with structural plastics is to develop an understanding not only of design techniques, but also of manufacturing and material behavior.

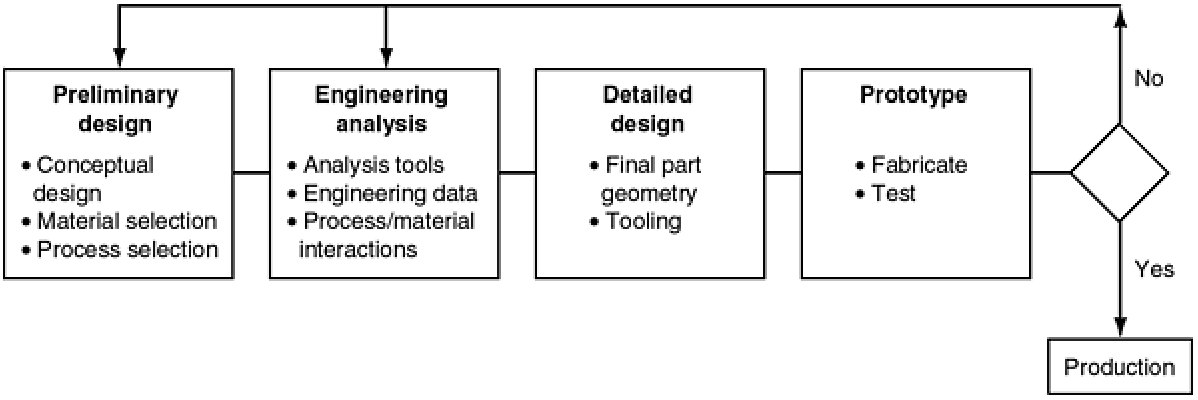

Fig. 1 Design-engineering process. The goal is to meet the end-use requirements the first time with the lowest cost.

Engineering thermoplastics exhibit complex behavior when subjected to mechanical loads. Standard data sheets provide overly simplified, single-point data that are either ignored or, if used, are probably misleading. Some databases provide engineering data (Ref 1) over a range of application conditions and knowledge-based material selection programs have been written (Ref 2). A methodology for optimal selection of materials and manufacturing conditions to meet part performance needs is being developed. This methodology is clarified in this article by describing and demonstrating simple tools and techniques for the initial prediction of part performance, leading to the optimal selection of materials and process conditions. Related coverage is provided in the articles "Effects of Composition, Processing, and Structure on Properties of Engineering Plastics" and "Design for Plastics Processing" in this Volume. Detailed information about many of the concepts described in this article can be found in *Engineering Plastics,* Volume 2 of the *Engineered Materials Handbook* published by ASM International.

Mechanical Part Performance

There are a wide variety of part performance requirements. Some, such as flammability, transparency, ultraviolet stability, electrical, moisture, and chemical compatibility, as well as agency approvals, are specified as absolute values or simplified choices. However, mechanical requirements such as stiffness, strength, impact, and temperature resistance cannot be specified as absolute values. For example, a part may be required to have a certain stiffness--maximum deflection for a given loading condition. The part geometry (design) and the material stiffness combine to produce the part stiffness. Thus, it is impossible to select a material without some knowledge of the part design. Similarly, the part may be required to survive a certain drop test and/or a certain temperature/time/loading condition. Again, it is impossible to select a material or design a part by using traditional, inadequate, single-point data such as notched Izod or heat distortion temperature (HDT). In addition, it is important to consider the effects of the design and material selection of a part on its fabrication (see the article "Relationship between Materials Selection and Processing" in this Volume).

Considerations such as flow and cycle time should be quantitatively included in the design and material-selection process. Simple yet extremely useful tools and techniques for the initial prediction of part performance are presented here.

The design process for thermoplastic part performance can be divided into two categories based on time-independent and time-dependent material behavior (Fig. 2). For time-independent material behavior, elastic material response is used to predict the displacement of a part under load. The maximum load occurs when the strength of the material is reached as fully plastic yielding for ductile materials or brittle failure for glass-filled materials. Time-dependent material behavior becomes important for three types of loading: monotonic loading at a given strain-rate until failure occurs, constant load for a period of time, or cyclic load. In the first case strain-rate-dependent material behavior becomes important; for constant load or displacement, time-dependent deformation or stress relaxation becomes an important design consideration; for cyclic loading, fatigue failure is an important consideration. In the next five sections, stiffness, strength, impact, creep/stress relaxation, and fatigue behavior will be related to part performance. More details of these important design issues can be found in Ref 3.

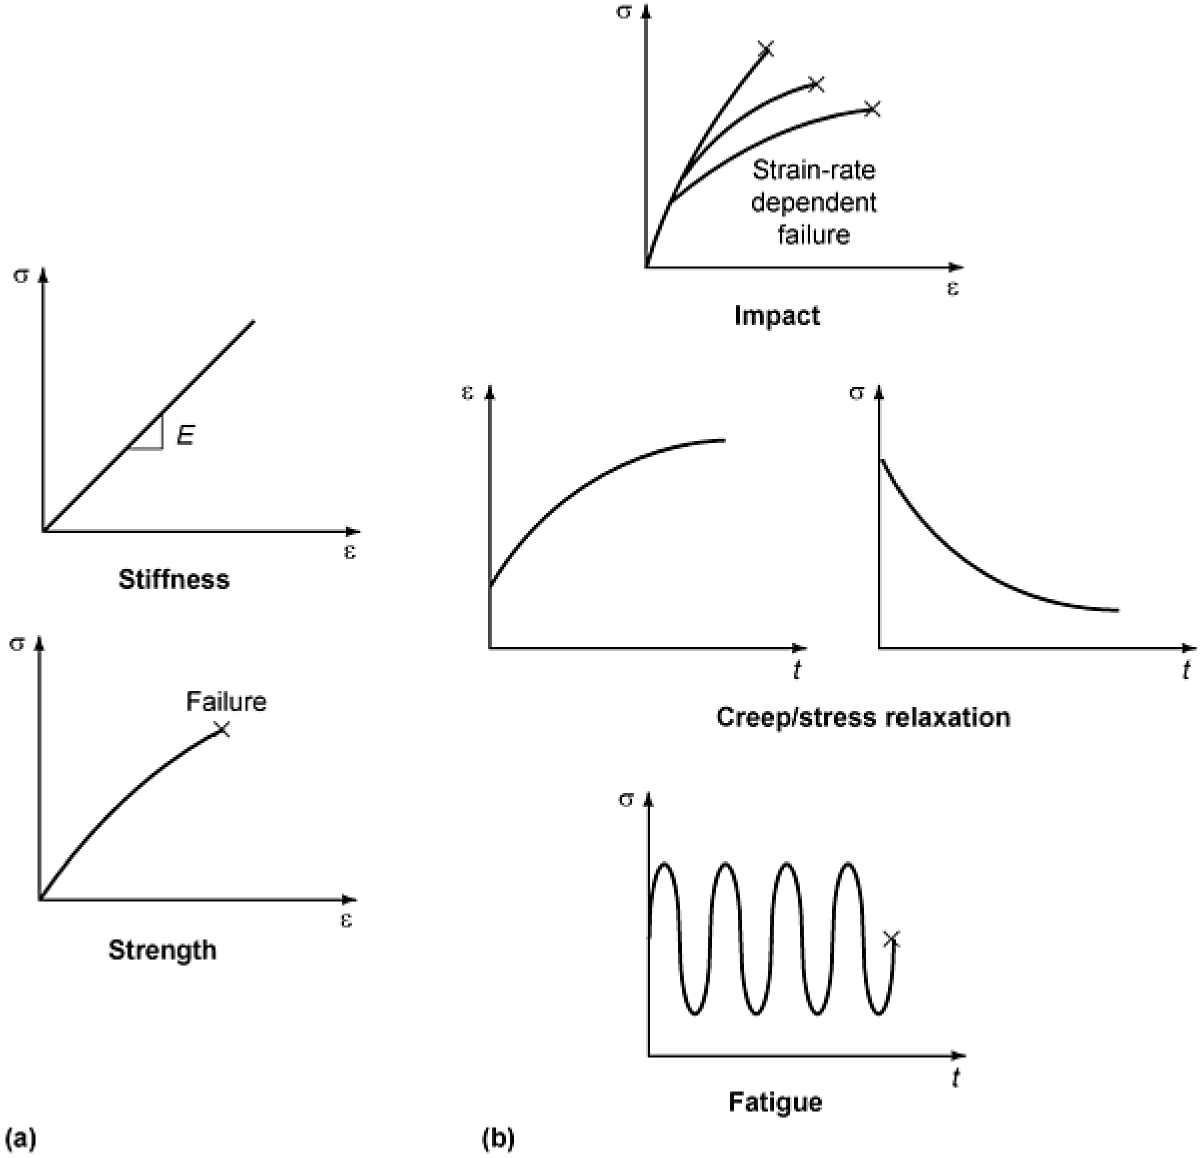

Fig. 2 Design for thermoplastic part performance. (a) Time-independent. (b) Time-dependent

Part Stiffness. Many thermoplastic parts are platelike structures that can be treated as a simply supported plate, possibly reinforced with ribs. A procedure intended to provide quick, approximate solutions for the stiffness of laterally loaded rib-stiffened plates has been developed (Ref 4). The computer program employs the Rayleigh-Ritz energy method and is capable of including the geometric nonlinearities associated with the large-displacement response typical of low-

modulus materials such as thermoplastics. The program allows the user to input the important parameters of specific plate structures (length, width, thickness, number of ribs, rib geometry), the boundary conditions (simply supported, clamped, point supported), and the loading (central point, uniform pressure, torsion loading). With the capability of multiple rib pattern definitions, the user can quickly determine the load-deflection response for different designs to select the one that is most effective for the specific application. This tool has been validated with finite element results. An example demonstrating the prediction of the nonlinear load displacement response is shown in Fig. 3.

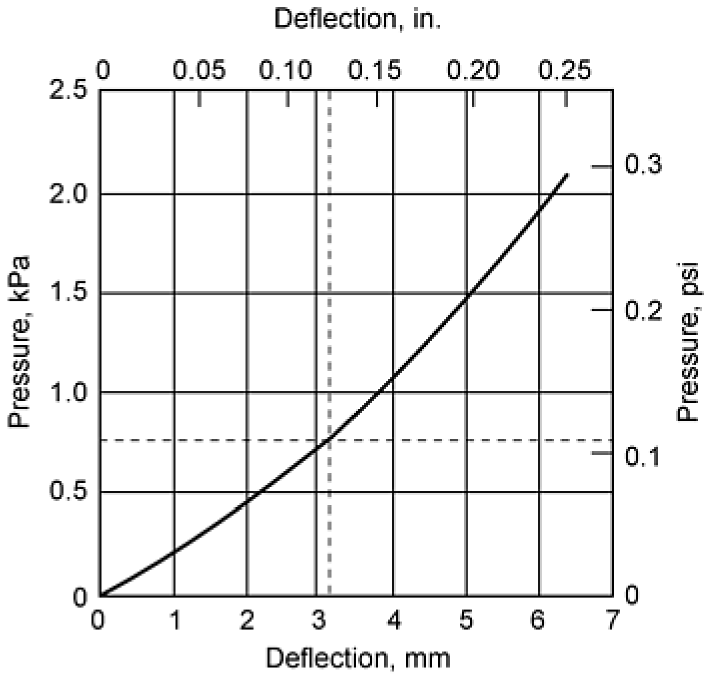

Fig. 3 Nonlinear pressure-deflection response for a 254 by 254 mm (10 by 10 in.) plate with a thickness of 2.5 mm (0.1 in.) and a material with a modulus of 2350 MPa (340 ksi)

Strength and Stiffness of Glass-Filled Plastic Parts. An accurate characterization of the strength and stiffness of glass-filled thermoplastics is necessary to predict the strength and stiffness of components that are injection molded with these materials. The mechanical properties of glass-reinforced thermoplastics are generally measured in tension using end-gated, injection-molded ASTM type I (dog-bone) specimens (Ref 3). However, the gating and the direction of loading of these molded specimens yields nonconservative stiffness and strength results caused by the highly axial orientation of glass that occurs in the direction of flow (and loading) during molding.

Previous studies (Ref 5) have shown that injection-molded, glass-reinforced thermoplastics are anisotropic; that is, stiffness and strength values in the cross-flow direction are substantially lower than in the flow direction. The tensile stiffness and strength were measured by using dog-bone specimens that were cut in both the flow and ross-flow direction from edge-gated plaques of various thicknesses. The ratio of the cross-flow/flow tensile modulus and strength of 30% glass-filled polybutylene terephthalate (PBT), 30% glass-filled modified polyphenylene oxide (M-PPO), and 50% glass-filled (long-glass fibers) nylon are plotted versus specimen thickness in Fig. 4 and 5. It is important to note the strong dependence of the cross-flow/flow ratio on specimen thickness and the small values of this ratio for small specimen thicknesses. These data clearly indicate that material selection and design for glass-filled materials that are based on injection-molded bars of a given thickness could be totally misleading--cross-flow properties could be only 50% of flow properties (small specimen thicknesses), and unless the thickness of the specimen is the same as the thickness of the part, the data could not be used for predicting part performance. However, for most parts (thickness less than 4 mm) with glass loadings of 30% or greater, a simple mold-filling analysis coupled with an anisotropic stress analysis with the cross-flow stiffness of 60% of the flow stiffness provides a reasonable prediction of part performance (Ref 3).

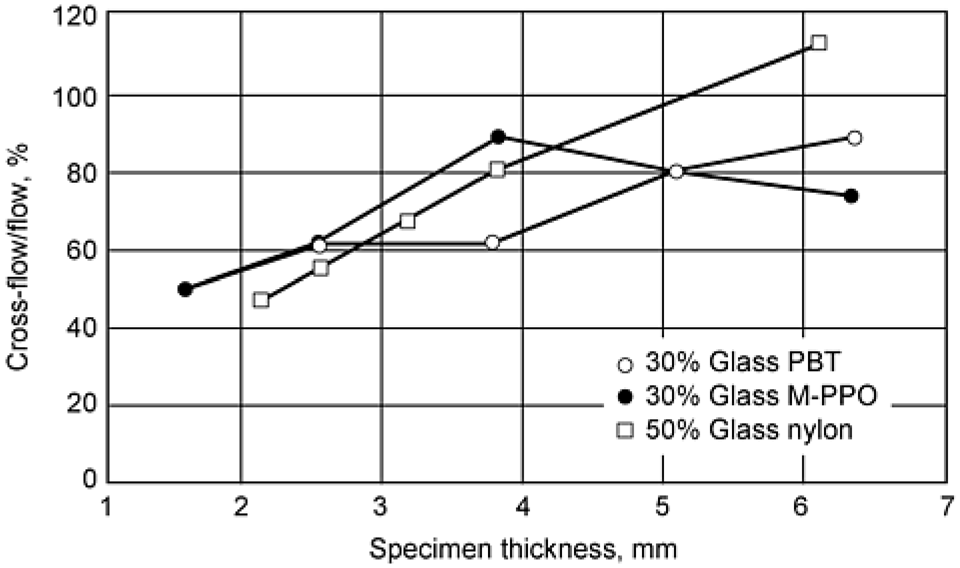

Fig. 4 Ratio of cross-flow/flow tensile modulus as a function of specimen thickness. PBT, polybutylene terephthalate; M-PPO, modified polyphenylene oxide

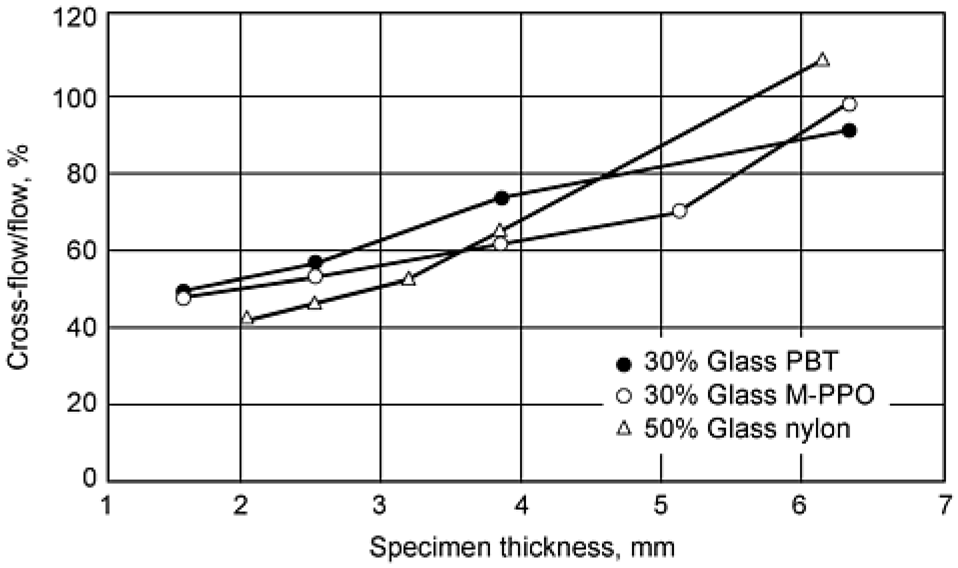

Fig. 5 Ratio of cross-flow/flow ultimate stress as a function of specimen thickness

Part Strength and Impact Resistance. A number of test methods such as Izod (notched beam) and Gardner/Dynatup (disk) are available for measuring impact resistance (Ref 3). Such tests should not only measure the amount of energy absorbed, but also determine the effects of temperature on energy absorption. Additionally, they should be able to identify strain-rate-dependent transitions from ductile to brittle behavior. They should be applicable to a wide variety of geometric configurations. Unfortunately, these techniques provide only geometry-specific, single-point data for a specific temperature and strain rate. Also, each test provides a different ductile/brittle transition. Energy absorption, however measured, is made up of many complex processes involving elastic and plastic deformation, notch sensitivity, and fracture processes of crack initiation and propagation.

The prediction of strength and impact resistance of plastic parts is probably the most difficult challenge for the design engineer. Tensile stress-strain measurements as a function of temperature and strain rate provide one piece of useful information. Most unfilled engineering thermoplastics exhibit ductile behavior in these tensile tests, with increasing strength (maximum stress) as displacement rate increases and/or temperature decreases. However, stress-state effects

must be added to the tensile behavior because the three-dimensional stress state created by notches, radii, holes, thick sections, and so forth increase the potential of brittle failure.

Ductile-to-brittle transitions in the fracture behavior of unfilled thermoplastics occur with increasing strain rates, decreasing temperatures, and increasingly constrained stress states. Figure 6 shows three common mechanical test techniques:uniaxial tension, biaxially stressed disks (usually clamped on the perimeter and loaded perpendicularly with a hemispherical tup), and notched beams loaded in bending. These three tests provide uniaxial, biaxial, and triaxial states of stress. Typical part geometries and loadings exhibit combinations of these states of stress. Thus, no one test is sufficient for part design and material selection. Furthermore, there are two competing failure modes: ductile and brittle (Fig. 6). With increasingly constrained stress states (uniaxial →biaxial →triaxial), the tendency for brittle failure tends to increase. Brittle failure occurs when the brittle failure mechanism occurs prior to ductile deformation (Fig. 6).

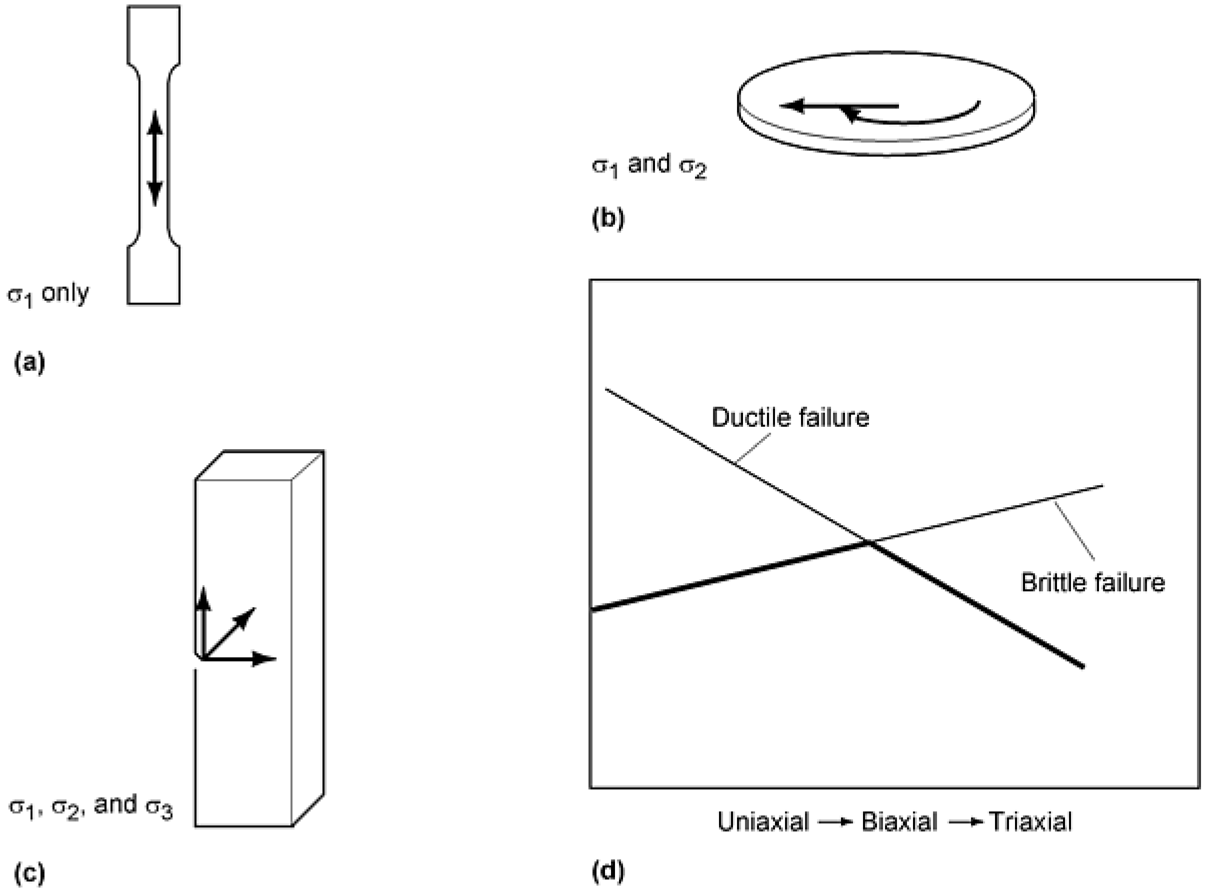

Fig. 6 Impact test methods exhibiting various states of stress. (a) Tensile test--uniaxial stress state. (b) Dynatup test--biaxial stress state. (c) Notch Izod test--triaxial stress state. (d) Competing failure modes

The calculation and measurement of the ductility ratio (Ref 6) is a method to characterize the ductility of a material for a relatively severe state of stress, for example, a beam with a notch radius of 0.25 mm (0.010 in.). The ductility ratio is defined as the ratio of the failure load in the notched-beam geometry ($P_{failure}$) to the maximum ductile, load-carrying capability in an unnotched-beam geometry where the height of the unnotched beam is equal to the net section height of the notched-beam geometry:

$$\text{Ductility ratio} = \frac{P_{failure}}{P_{ductile}} \quad \textbf{(Eq 1)}$$

where:

$$P_{\text{ductile}} = \frac{\sigma_f bh^2}{l} \quad \textbf{(Eq 2)}$$

and σ_f is the strength at appropriate rate and temperature, *b* is the beam thickness, *h* is the beam height, and *l* is the beam span.

This ductile load limit can be determined experimentally or with this plastic-hinge calculation assuming fully developed plasticity over the entire cross section and perfectly plastic material behavior. A ductility ratio of 1.0 corresponds to a ductile failure, while ductility numbers less than 1.0 correspond to varying levels of brittle behavior. Ductility ratios can be plotted as a function of strain rate at different temperatures to create fracture maps such as the one shown for polycarbonate (PC) in Fig. 7. This information is useful for material-selection and initial part design considerations.

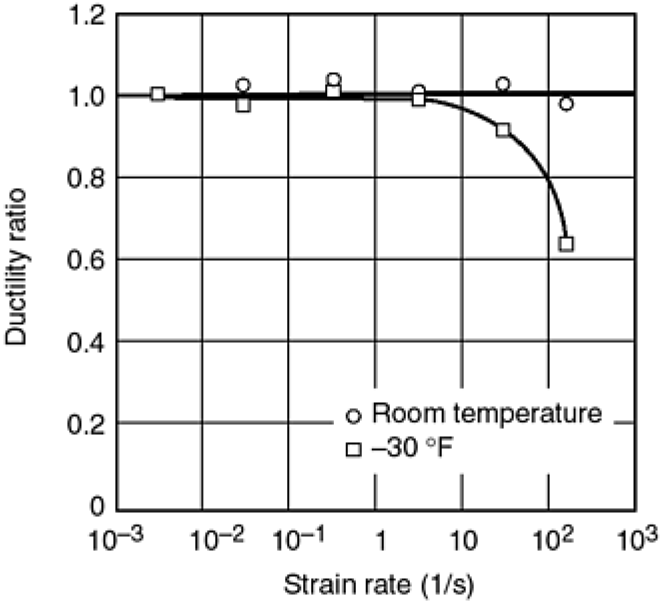

Fig. 7 Fracture map for polycarbonate

Creep/Stress Relaxation--Time/Temperature Part Performance. Polymers exhibit time-dependent deformation (creep and stress relaxation) when subjected to loads. This deformation is significant in many polymers, even at room temperature, and is rapidly accelerated by small increases in temperature. Hence, the phenomenon is the source of many design problems. Development and application of methods are needed for predicting whether a component will sustain the required service life when subjected to loading, as the useful life of the part could be terminated by excessive deformation or even rupture. For most practical applications of polymers, predictive methods must account for part geometry, loading, and material behavior.

A common measure of heat resistance is the heat distortion temperature (HDT). For this test, bending specimen 127 by 12.7 mm (5 by 0.5 in.) with a thickness ranging from 3.2 to 12.7 mm (0.125 to 0.5 in.) is placed on supports 102 mm (4 in.) apart, and a load producing an outer fiber stress of 0.46 or 1.82 MPa (66 or 264 psi) is applied. The temperature in the chamber is increased at a rate of 2 °C/min (3.6 °F/min). The temperature at which the bar deflects an additional 0.25 mm (0.010 in.) is called the HDT or sometimes the deflection temperature under load (DTUL). Such a test, which involves variable temperature and arbitrary stress and deflection is of no use in predicting the structural performance of a thermoplastic at any temperature, stress, or time. In addition, it can be misleading when comparing materials. A material with a higher HDT than another material could exhibit more creep at a lower temperature. Also, some semicrystalline materials exhibit very different values of HDT at 0.46 and 1.82 MPa (66 and 264 psi). For example, with PBT, the HDT at 0.46 MPa (66 psi) is 154 °C (310 °F), and the HDT for 1.82 MPa (264 psi) is 54 °C (130 °F). The question of which HDT to use for comparison with another material that has the same HDT for both stress levels naturally arises. Another approach that is often used to account for the change in material modulus with temperature is the use of dynamic mechanical analysis (DMA) data (Ref 7). Although this approach may be a more useful indication of instantaneous

modulus variation with temperature than HDT, it is unable to account for the time-dependent nature of most applications. For purposes of predicting part performance and for material selection, tensile creep data are the desired measurements.

To be useful for preliminary part design and material selection, creep data must be converted to simple information such as "deformation maps." A simple method is summarized where linear elastic part deformations are simply magnified by the use of deformation maps thus accounting for time and temperature effects.

A deformation map is produced directly from creep data (Ref 8). For a given temperature, T, the measured time-dependent strain, $\varepsilon(t)$ is divided by the applied stress, σ, to determine the creep compliance, J, as:

$$J(T,t) = \frac{\varepsilon(t)}{\sigma} \qquad \textbf{(Eq 3)}$$

The creep compliance is then normalized by dividing by the room temperature (T_0), instantaneous ($t \rightarrow 0$), elastic compliance, $J(T_0, 0)$:

$$\hat{J} = \frac{J(T,t)}{J(T_0, 0)} \qquad \textbf{(Eq 4)}$$

Because $J(T_0, 0)$ is the inverse of the room-temperature elastic modulus, E:

$$\hat{J} = J(T,t) \cdot E \qquad \textbf{(Eq 5)}$$

and

$$\hat{E} = \frac{1}{\hat{J}} \qquad \textbf{(Eq 6)}$$

Thus, a deformation map in time and temperature space can be produced from creep data with lines of constant compliance and modulus (Fig. 8). Thus, the design process involves calculating the linear elastic part deformation using E and then magnifying that deformation by $\hat{J}$ for the time of loading and ambient temperature. When a constant displacement is applied to a part, the calculated linear elastic stress using E is then reduced by $\hat{E}$ for the time of interest and ambient temperature. Thus, the deformation map provides a simple method to predict the time-dependent performance of plastic parts. As shown in Fig. 8, the deformation map provides the material response that can be combined with a linear elastic, time-independent analysis (in this case a finite-element stress analysis) to predict the time-dependent deformation. Validation of this approach is demonstrated by comparing it to experimentally measured part deformations (Fig. 8).

Fatigue-Cycle-Dependent Part Performance. An understanding of the deformation and fracture behavior of plastics subjected to cyclic loading is needed to predict the lifetime of structures fabricated from thermoplastics. This fatigue behavior is of concern because failure at fluctuating load levels can occur at much lower levels than failure under monotonic loading. A significant amount of information exists on the fatigue behavior of plastics. Unfortunately, very little has been documented about the application of this understanding to the prediction of the fatigue behavior of plastic parts.

There are two distinct approaches to treating and measuring the fatigue of polymers. The first approach is the traditional measurement of the number of cycles to failure (N) as a function of the fluctuating load or stress (S), that is, S-N. The "load" that is controlled is the minimum and maximum force or displacement in tension or bending. The fluctuations have a certain frequency and waveform. From a design viewpoint, it is difficult to predict part performance with these data because an enormous number of variables must be taken into consideration as well as various environmental conditions and a wide variety of materials.

The second approach to treating the fatigue of plastics is cyclic crack propagation. The use of fracture mechanics in cyclic fatigue involves the measurement of the amount of crack growth per cycle as a function of the stress-intensity factor. The fundamental addition here is the treatment of the crack length and thus an improved understanding of a fatigue mechanism. However, the same large number of variables that apply to the traditional fatigue (S-N) approach apply to the crack propagation approach. In addition, the design engineer is challenged with determining the initial or inherent flaw size.

Even though cycle-dependent part performance is not well understood, a general design-engineering approach can be applied to the fatigue of plastic parts. First, for material selection an awareness of the fatigue performance of numerous plastics is necessary. Materials should be compared under identical test conditions to determine their relative fatigue performance. This preliminary selection should be based on the general assessment of the relative fatigue performance, taking into account the overall severity of the part loading. Next, the part loading conditions should be determined and related to the appropriate laboratory data. This task is probably the most important, yet the most difficult due to the large number of variables involved. Establishing whether the part will experience load-controlled or displacement-controlled cyclic loadings is possibly the most significant factor. Next, the effects of frequency, waveform, and load level and type must be assessed to determine if part temperature will increase, leading to thermal fatigue, or if mechanical failure will occur with little or no temperature increase. Other conditions that should be considered or matched from the laboratory specimen to the component include environmental effects (e.g., temperature), stress state, stress concentrations, and mean stress. Finally, appropriate laboratory tests or full-scale component tests should be conducted. These laboratory tests must be carefully planned to achieve correspondence to the actual service conditions.

Fracture mechanics can be used to provide an approach to predicting the fatigue lifetime of components. The important additional feature is an understanding of crack growth through measurement of the amount of crack growth per cycle (da/dN) as a function of the cyclic range of stress-intensity factors (ΔK). Despite the fact that plastics are time-dependent materials, and that linear fracture mechanics only apply strictly to elastic materials, it appears that crack propagation rates in many polymers can be correlated with ΔK.

During the fatigue process, the stress amplitude ($\Delta\sigma$) usually remains constant and failure occurs as the result of crack growth from an initial, subcritical size to a critical size related to the fracture toughness (K_c) of the material. The lifetime of a component is thus dependent on the initial crack size, the rate of crack growth, and the critical crack size. The relation takes the power-law form:

$$\frac{da}{dN} = A\ \Delta K^n \qquad \textbf{(Eq 7)}$$

where A and n are material constants varying with temperature, environment, and frequency. The stress-intensity factor range is given as:

$$\Delta K = Y(\Delta\sigma)\sqrt{a} \qquad \textbf{(Eq 8)}$$

where Y is a crack and structural geometry factor and a is crack length. Typical crack propagation curves for a number of plastics (Ref 9) are shown in Fig. 9.

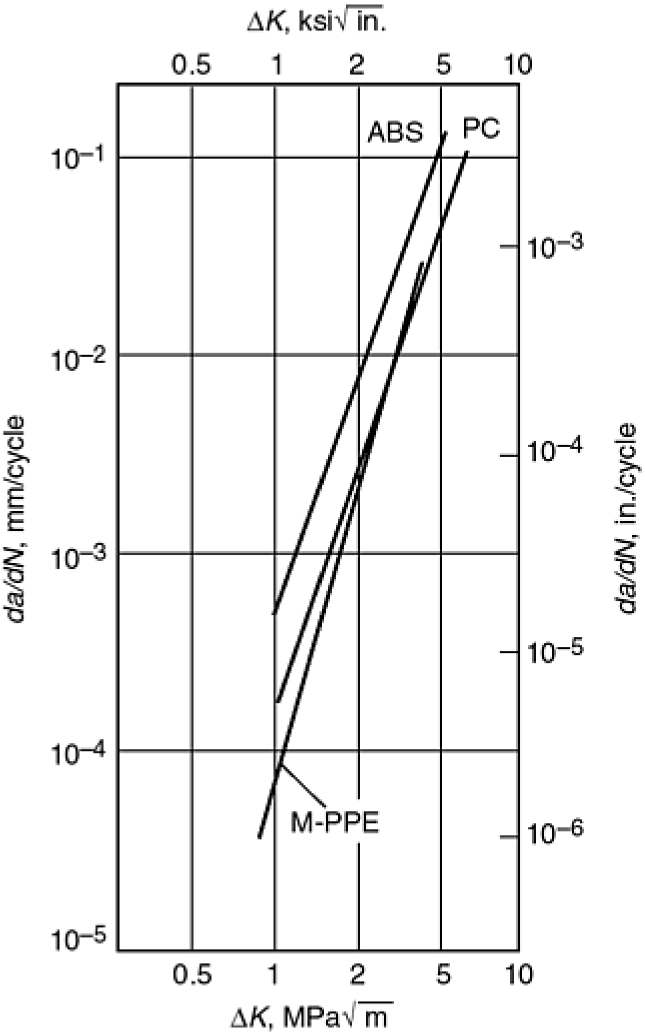

Fig. 9 Fatigue crack propagation behavior. ABS, acrylonitrile-butadiene-styrene; PC, polycarbonate; M-PPE, modified polyphenylene ether

Fatigue lifetime of plastic parts can be calculated for design purposes by integrating the crack-growth rate expression (Eq 7) after substitution of Eq 8:

$$\frac{da}{dN} = AY^n \Delta\sigma^n a^{n/2} \quad \textbf{(Eq 9)}$$

Assuming that the geometry factor *Y* does not change as the crack grows, this equation can be integrated to give the number of cycles to failure (N_f) that is necessary for the crack to grow from its initial size a_i to the critical size a_f. For $n \neq 2$:

$$N_f = \frac{2}{(n-2)AY^n \Delta\sigma^n}\left(\frac{1}{a_i^{(n-2)/2}} - \frac{1}{a_f^{(n-2)/2}}\right) \quad \textbf{(Eq 10)}$$

This expression can be used to predict the fatigue lifetime of a component with an initial defect of known size.

The fatigue lifetime (number of cycles-to-failure) of a part is strongly dependent on the applied load. *S-N* curves have been generated for a number of thermoplastics (Ref 10) at room temperature with a standard tensile specimen with a net cross section of 12.7 by 3.2 mm (0.5 by 0.125 in.). The tensile load was varied from a very small load (nearly zero) to

various maximum loads (stresses). A sinusoidal waveform with a frequency of 5 Hz was used. Very little or no specimen heating occurred. By choosing *S-N* curves for the same materials--polycarbonate (PC), modified polyphenylene ether (M-PPE), and acrylonitrile-butadiene-styrene (ABS)--whose fatigue crack propagation behavior is displayed in Fig. 9, the *S-N* data can be combined with the crack propagation data to compute the initial crack lengths (Eq 10). The final crack length a_f is computed from the fracture toughness of these materials. Thus, over the range of stresses for the *S-N* curves, the initial crack lengths can be computed. Ideally, these crack lengths would be independent of applied stress level. However, while there is some variation, the average crack length was computed and used in Eq 10 to "predict" the measured *S-N* data from the crack growth rate data. These results are shown in Fig. 10 for PC, M-PPE, and ABS. These data and this approach indicate the similarity of the *S-N* and crack growth rate methods of predicting part lifetime and suggest a method of utilizing both types of data.

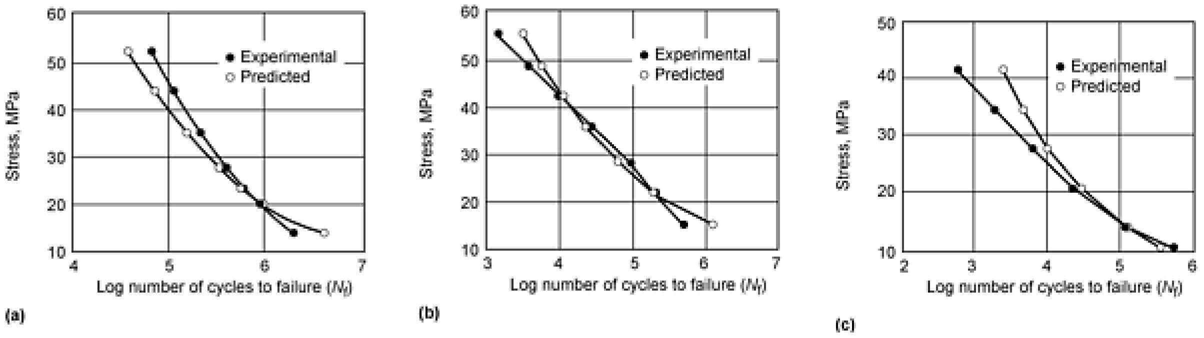

Fig. 10 *S-N* data compared to crack growth prediction. (a) PC; a_i = 0.013 mm. (b) M-PPE; a_i = 0.32 mm. (c) ABS; a_i = 0.23 mm

Manufacturing Considerations

Flow Length Estimation. The ability to manufacture plastic parts using the injection-molding process is governed by the material behavior, part geometry, and processing conditions. Estimating the flow length of the resin into a mold of a

given thickness is an important manufacturing consideration for the design engineer. An example is given here of a generic tool (Ref 11) capable of analyzing radial flow and quantifying effects of material, geometry, or process changes. This tool, Diskflow, is composed of a numerical flow analysis, automatic mesh generator, and menu-driven pre- and postprocessors. No knowledge of simulation techniques is required, though a knowledge of injection molding is needed when interpreting the results.

Diskflow utilizes modeling techniques common to most commercial analyses (see the article "Computational Fluid Dynamics" in this Volume), yet is much faster due to the radial flow assumption and subsequent numerical methods. Modeling, postprocessing, and computer analysis time have been minimized, reducing total analysis time. This analysis cannot replace three-dimensional filling analyses as it does not yield any information regarding knit-line and gas trap locations, cavity pressure and temperature distributions, or more complex mold geometries, but it does yield significant results regarding design feasibility, material performance, and process effects.

Diskflow uses complete viscosity versus shear rate and temperature data fit with a modified Cross model with Williams-Landel-Ferry (WLF) temperature dependence when available. If this advanced model is not available, the Arrhenius model is employed. Mold and melt temperatures can be chosen if default values are not adequate. The mold geometry is defined in terms of a nominal wall thickness and cavity radius that can be calculated by entering cavity volume or projected area. The sprue is defined by entering the sprue type (hot or cold) and then entering the length, upper diameter, and lower diameter.

For flow length estimation, an initial flow rate is assumed constant subject to some user-specified maximum pressure limit that mimics the capability of a molding machine. As the mold fills at a constant volumetric flow rate, the injection pressure rises due to the increasing flow resistance. When the injection pressure attains the user-specified maximum, the analysis switches over to a second phase in which the injection pressure is maintained at a constant value and the flow rate is allowed to vary; the flow rate eventually decays to zero at which point a final flow length is attained. The flow length may be defined as the farthest distance that a polymeric material travels in a mold of some nominal wall thickness given a set of processing conditions. The flow length capability examines the feasibility of manufacturing a desired design: if the distance from the gate to the corner of the part is greater than the predicted flow length, then the part may not be manufacturable. Figure 11 shows the dependence of flow length on wall thickness for a maximum injection pressure of 103.5 MPa (15 ksi) for PC. This information is useful for assessing manufacturability in the early stages of design and material selection.

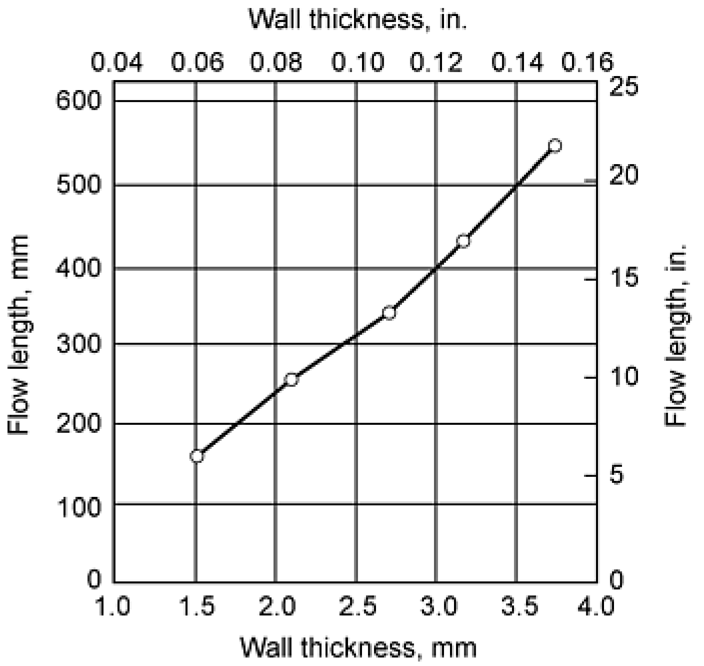

Fig. 11 Flow length versus wall thickness predicted by Diskflow mold-filling analysis. Material, unfilled PC; mold temperature, 82 °C; melt temperature, 335 °C; maximum injection pressure, 103.4 MPa

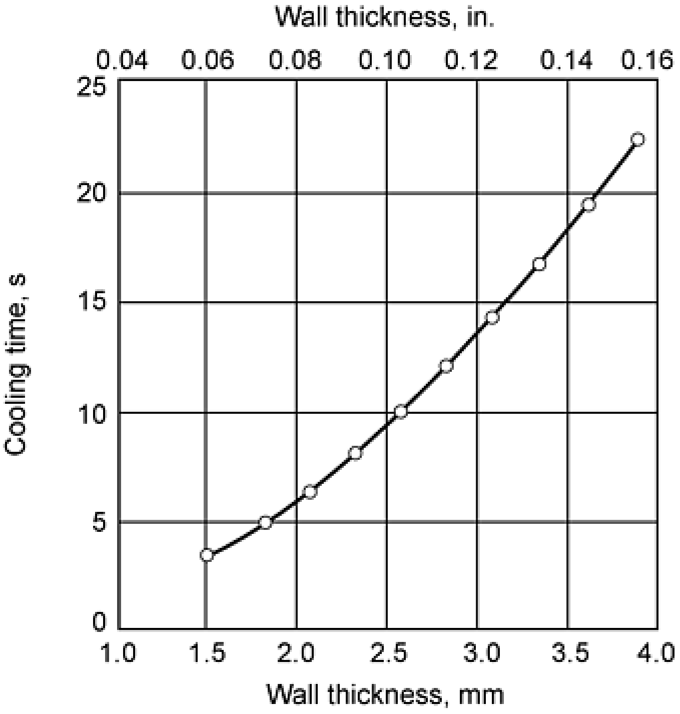
Cycle Time Estimation. The molding of thermoplastics consists of injecting a molten polymer into the cooled mold cavity. The injected resin is held in the cavity until the part solidifies (by heat transfer). The time for the melt to cool until it solidifies to the extent that the part can be removed from the mold and retain its dimensions is generally the majority of the total cycle time. The large impact of the cooling time on the total processing cost is obvious.

During the cooling phase, heat conduction is the prime mechanism of heat transfer. The development of a simplified mold-cooling program allows designers and molders to evaluate materials and process parameters in a rapid, convenient, and cost-efficient manner. Plastic parts are usually thin, and thus a one-dimensional, transient heat conduction analysis is adequate to approximate the cooling of the real part. The main assumption is that the mold surface is kept at a constant temperature throughout the cooling phase. Comparing calculated minimum cooling times for different material part geometries (i.e., thickness) and processing conditions help optimize the material-selection process.

Thermal material properties are strong functions of temperature. Because the thermoplastic material experiences a wide range of temperatures during the cooling phase, temperature-dependent material data such as specific heat and thermal conductivity are used for the computations. To perform the analysis the injection temperature, mold temperature, ejection temperature, material, and thickness must be chosen. The program uses a one-dimensional finite-difference scheme to calculate temperature through the thickness as a function of time. When the center of the plate reaches the specified ejection temperature, the analysis is stopped and the results are displayed graphically. By performing the analysis for a range of part thicknesses, cooling time curves can be produced (Fig. 12). These curves can then be used to estimate cycle times in the early stages of material selection and design.



Material	Unfiled PC
Thickness, mm	1.62-3.81
Thermal Conductivity, W/m · K	0.270
Specific heat, W · s/kg · K	1791
Melt temperature, °C	300
Mold temperature, °C	82
Ejection temperature, °C	112

Design-Based Material Selection

Design-based material selection (Ref 12, 13) involves meeting the part performance requirements with a minimum system cost while considering preliminary part design, material performance, and manufacturing constraints (Fig. 13). Some performance requirements such as transparency, Food and Drug Administration (FDA) approval, or flammability rating are either met by the resin or not. Mechanical performance such as a deflection limit for a given load are more complicated requirements. Time- and temperature-reduced stiffness of the material is determined from the deformation map. Part design for stiffness involves meeting the deflection limit with optimal rib geometry and part thickness combined with the material stiffness. This part geometry can be used to compute the part volume that when multiplied by the material cost provides the first part of the system cost. The second half of the system cost is the injection-molding machine cost multiplied by the cycle time. This total system cost is a rough estimate used to rank materials/designs that meet the part performance requirements. In addition, the manufacturing constraint of flow length for the part thickness must be considered. The entire process is summarized in Fig. 13.

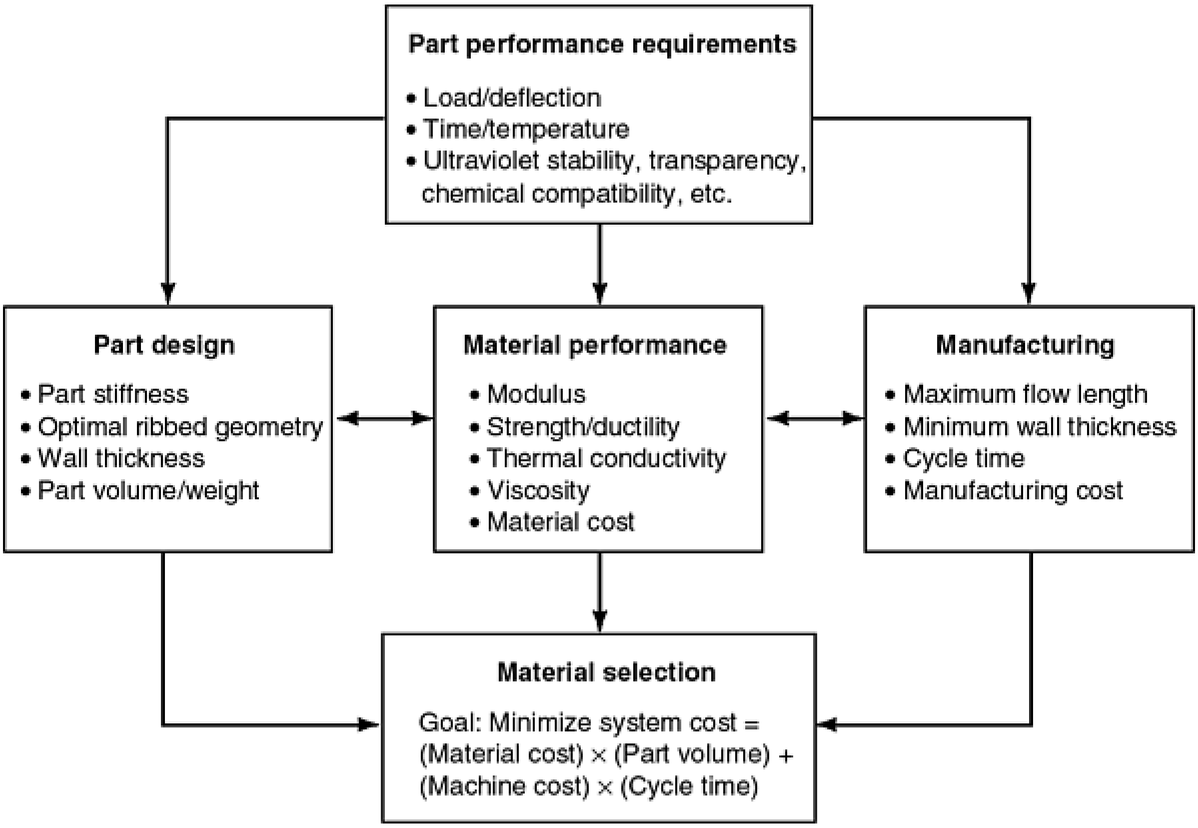

Fig. 13 Design-based material-selection process

Example 1: Materials Selection for Plate Design.

A simple example is presented to illustrate the design-based material-selection process. A 254 by 254 mm (10 by 10 in.) simply supported plate is loaded at room temperature with a uniform pressure of 760 Pa (0.11 psi). The maximum allowable deflection is 3.2 mm (0.125 in.). Using the program Ribstiff, described previously in the part stiffness section, the nonlinear load-displacement response of the plate can be computed. Through iteration, it is determined that a PC plate with a thickness of 2.5 mm (0.1 in.) satisfies the requirements (Fig. 3). From Fig. 11, the flow length is 320 mm (12.5 in.). Thus, the plate could be filled with a center gate or from the center of an edge. From Fig. 12, the in-mold cooling time is 10 s. The volume of the plate is 0.00016 m^3 (10 $in.^3$).

A second design can be produced by designing a rib-stiffened plate. Again, through iteration, a 1.5 mm (0.060 in.) thick plate with 10 ribs in each direction with a rib height of 4.5 mm (0.18 in.) and a rib thickness of 1.5 mm (0.060 in.) would meet the deflection requirement. From Fig. 11, the flow length is about 175 mm (7 in.). Thus, because a center-gated plate would have a flow length of 175 mm (7 in.), the part would probably fill if the ribs would serve as flow leaders to aid the flow. However, it is generally not recommended to push an injection-molding machine to its limits because this will exaggerate inconsistencies in the material and the process. A more thorough three-dimensional process simulation should be performed to determine the viability of this design before it is chosen. From Fig. 12, the in-mold cooling time is about 4 s, a considerable savings (6 s/part) in cycle time as compared to the plate with no ribs. In addition, the volume of the ribbed plate is 0.00013 m^3 (8 $in.^3$), a saving of 20% on material as compared to the plate with no ribs. The system cost of the ribbed plate is computed to be 73% of the plate with no ribs (Fig. 1). Because the ribs would produce a constrained, three-dimensional stress state, consideration of impact would be important for high rates of loading and low temperature (Fig. 7). The fracture map shows a tendency for brittle behavior with PC at low temperature and high loading rates for notched or constrained geometries.

If time/temperature performance were added to this example as a requirement, the optimal material may change or the initial design would need to be modified. If the same load were applied to the plate for 1000 h at a temperature of 79 °C (175 °F), the PC plate would exhibit a deformation as if its material stiffness were about 40% of the room-temperature modulus (Fig. 8). Simply increasing the thickness of the plate with no ribs to 3.5 mm (0.136 in.) would provide a design that would meet the deflection requirements. The penalty would be a 40% increase in material usage and an additional 8 s added to the cycle time. Choosing a material with more temperature resistance or initial stiffness is an option.

Example 2: Materials Selection for an Electrical Enclosure.

The usefulness of this process can be demonstrated through another design example. In this case, a very simple five-sided box is chosen. The box is used as an electrical enclosure and must meet flammability requirements. This limits the number of candidate materials to examine more closely. Also, this enclosure is not painted and, therefore, the resin must be unfilled to maintain acceptable aesthetics. It is unribbed to minimize sink marks on the exposed surfaces. Finally, it must support a uniform load across its surface without deflecting more than 2.5 mm. The enclosure is a 300 mm wide by 450 mm long by 100 mm high box (Fig. 14).

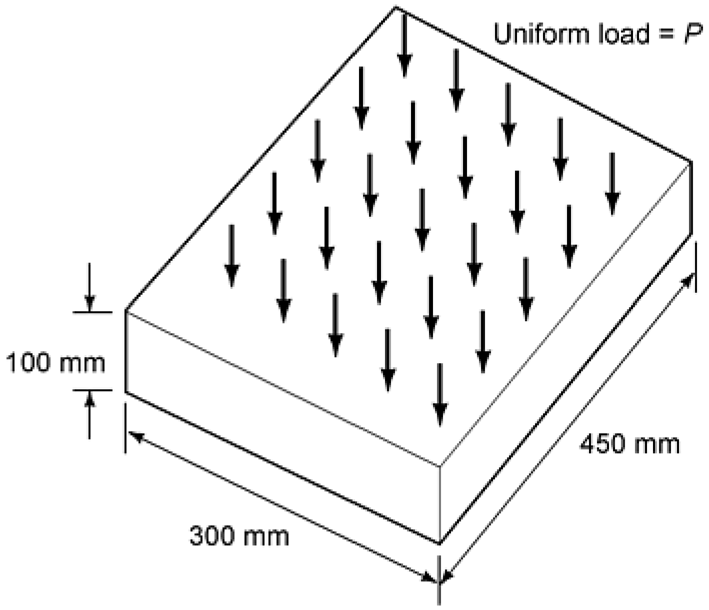

Fig. 14 Geometry of enclosure example

A series of analyses is performed using three resins to see how they perform under different conditions. These resins are representative of what is currently used in electrical enclosures (computer housings, office equipment, etc.). They are an unfilled M-PPO resin, an unfilled ABS resin, and an unfilled PC-ABS resin blend.

To examine the relative performance of each resin, the application requirements are varied in loading, environment, and manufacturing. First, the uniform load is varied from 150 to 1200 Pa. Next, the ambient temperature the enclosure must withstand for 1000 h under load is varied from 20 to 80 °C. Finally, the gating scenario is changed from edge gated to center gated to multiple gates.

Using a center-gated box at 40 °C for 1000 h, the uniform load is varied from 150 to 1200 Pa. The Design-Based Material Selection Program determines for each resin the optimal wall thickness to support the load at the lowest variable system cost for each loading case. Figure 15(a) compares the normalized cost of the enclosure for each resin as the load is increased. As can be seen from this graph, the PC-ABS and M-PPO are virtually equivalent in cost, while the ABS is about 30% more expensive. While this may seem counterintuitive (ABS is less expensive per pound than PC-ABS or M-PPO), it is easily explained by examining Fig. 15(b), wall thickness versus loading. At this elevated temperature and long time (40 °C, 1000 h), the ABS requires significantly more material to support the required load within the specified 2.5 mm deflection than either the PC-ABS or the M-PPO. This added material far outweighs the price advantage of ABS.

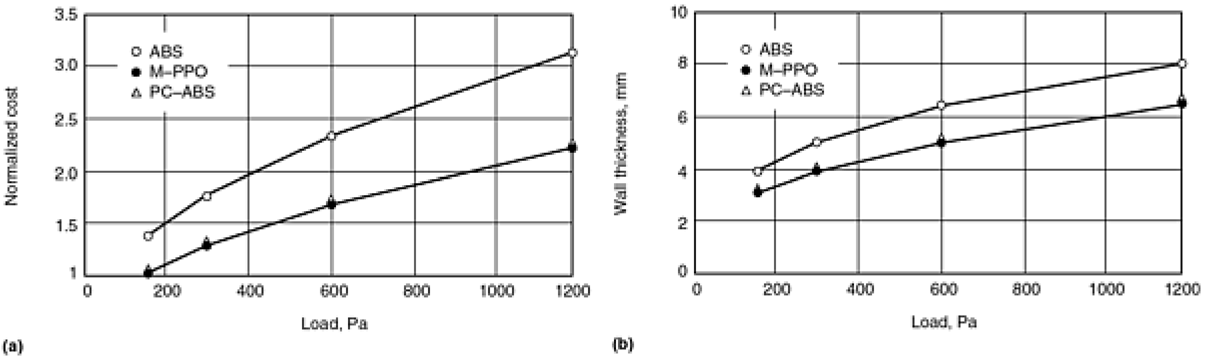

Fig. 15 Loading variation for 40 °C and 1000 h

The cooling time is another factor that will increase the variable system cost of the ABS resin enclosure. As the wall thickness increases, the time to cool the part to ejection temperature will increase. The cooling time is also influenced by the thermal properties of each resin. Figure 16 contains a graph of the cooling time versus wall thickness for the three example materials based on one-dimensional transient heat-transfer analyses. The wall thickness for each resin to support 600 Pa at a deflection of no more than 2.5 mm is indicated on the graph. From this graph, it can easily be seen that, in this case, the cooling time for each resin will be very different.

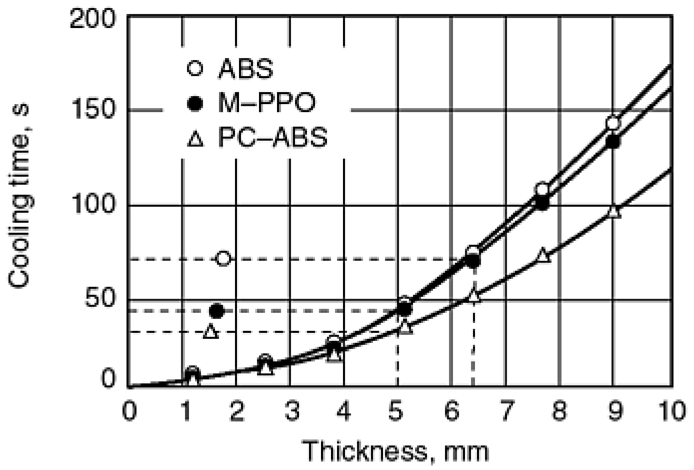

Fig. 16 Cooling time versus wall thickness

Using a center-gated box that must support a 300 Pa load within a 2.5 mm deflection of 1000 h, the temperature was varied from 20 to 80 °C. Figure 17(a) compares the normalized cost of these three resins as the temperature is increased. Initially, at 20 °C these resins have very similar variable system costs. As the temperature increases, the creep performance of each resin decreases. Figure 17(b) shows the creep modulus for each resin as the temperature changes. The creep modulus of the ABS resin decreases rapidly as temperature increases. The M-PPO maintains its stiffness longer, but eventually decreases rapidly while the PC-ABS performs better, because of the high creep resistance of the PC component of the blend.

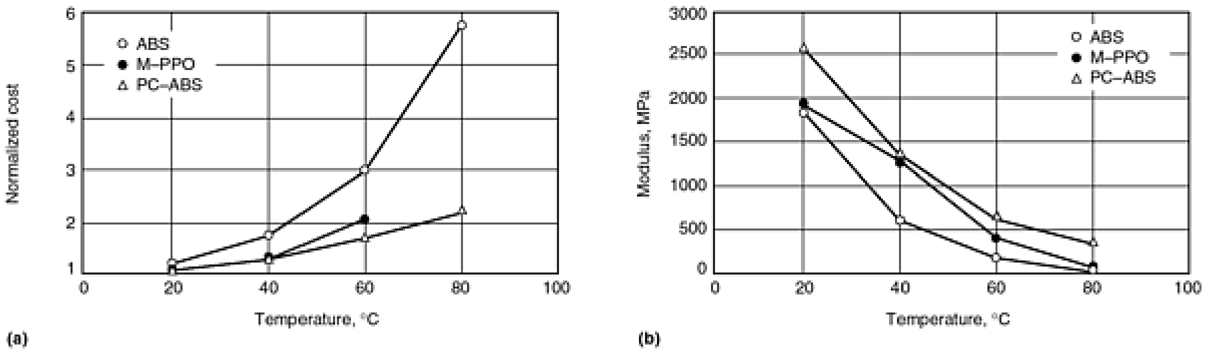

Fig. 17 Temperature variation

The wall thickness to support the load must increase as temperature increases because the creep modulus decreases. This, in turn, increases the part volume and the cooling time, affecting the variable system cost. As the temperature increases, the cost rises to high levels (ABS at 80 °C, 1000 h). If the application must withstand these temperature extremes, a higher-performance thermoplastic may be a better choice.

The process to manufacture this enclosure can influence how the enclosure will be designed and what material will be used. Using a box that must support a 150 Pa load within a 2.5 mm deflection in a 40 °C environment for 1000 h, the gating scenario is varied choosing three common configurations (Fig. 18) edge gate, center gate, and four gates. The minimum flow length necessary to fill the part is determined for each case based on the geometry of the enclosure and the gate position. The minimum flow length necessary to fill the part is determined for each case based on the geometry of the enclosure and the gate position. The minimum wall thickness to allow each material to achieve this flow length, determined using the radial flow injection molding simulation, is then used as a lower bound on the thickness optimization and is shown in Fig. 19(b). Figure 19(a) details the normalized cost versus minimum flow length (i.e., gating scenario). Initially, as the flow length increases (from four gates to center gate) the normalized cost does not change. The

wall thickness necessary to support the load within the specified deflection is greater than the minimum wall thickness dictated by the flow length constraint. As the flow length increases from the center-gated to the edge-gated case, the normalized cost increases because the wall thickness is now dictated by the manufacturing constraint rather than the loading condition. The gate placement now dictates the wall thickness that is necessary to fill the part.

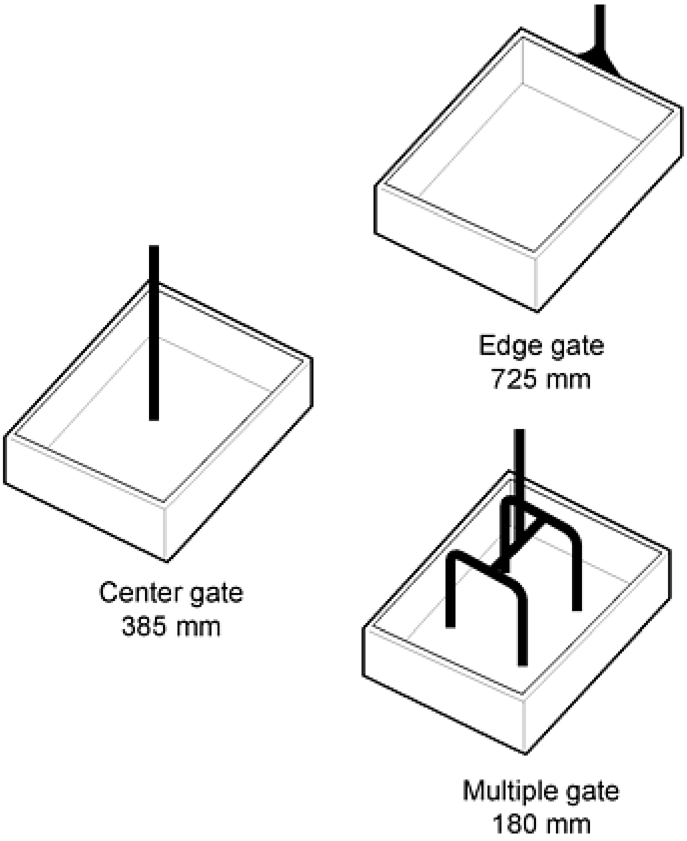

Fig. 18 Examples of gating scenarios

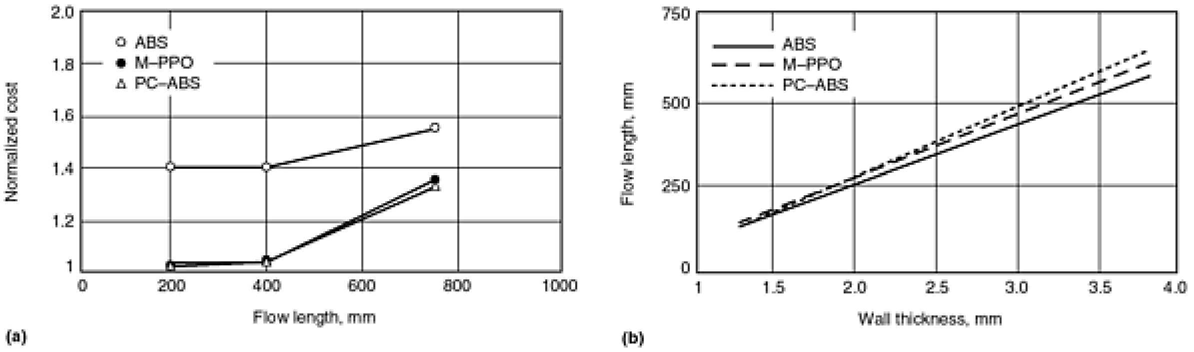

Fig. 19 Gating variation

There are other considerations that a design engineer can use to help determine the best material for an application. The strength of a resin over a range of temperatures may aid the engineer in determining if the part will fail under load. The impact performance of the resin, as indicated by the ductility ratio, can also be quite important. While it only indicates the impact performance for one specific geometry, and cannot be used in design, it does provide useful comparative information.

Conclusions

The goal of the design engineer is to achieve the lowest system (design/material/process) cost while meeting the part performance requirements. Material selection and engineering design of plastic parts is a difficult task because of a lack of effective and efficient design methods and the associated material data. However, there are now some new methods that will improve the design process by providing more accurate and effective predictive techniques. Fracture maps indicate the relative ductility of a material as a function of temperature and strain rate for a relatively severe stress state. A range of test data for different stress states from tensile tests, disk tests, and notched beams is used to predict part deformation and potential ductile-to-brittle behavior. For time-dependent deformation, such as creep or stress relaxation, deformation maps can be combined with linear-elastic calculations of part deformation to predict the time- and temperature-dependent deformation of the part. The cross-flow stiffness and strength of injection-molded glass-filled materials is sometimes only 50% of the stiffness and strength in the flow direction, especially for thin-walled parts. This must be accounted for in predicting part stiffness and strength. For predicting lifetime of parts subjected to cyclic loading, the combination of *S-N* data and crack growth rate data is useful because it provides two options: to use the *S-N* data directly or to use the initial defect size with the crack growth rate data. In either case, with the vast number of parameters that affect fatigue behavior, having more information is useful. The design methods and material data summarized here provide the design engineer with more effective and efficient techniques to select materials and design plastic parts.

Introduction

THE QUEST for improved performance has caused designers to search for materials with lower density, higher modulus, and higher theoretical strength than the common engineering metals. There are a number of elements and compounds, all centered around carbon in the periodic table, that have lower density and high modulus and strength. All are brittle ceramic materials with the exception of beryllium. The specific modulus (modulus/density) provides an indication of performance for a stiffness-limited application and for pure tensile applications in which weight is important (Fig. 1). The theoretical tensile strength of a brittle material is approximately 0.2 of the elastic modulus, so the same materials that have high modulus have the potential for high strength. Practically, many of these materials have been made in fiber form with high tensile strength, although with much lower strength than the theoretical values (Fig. 2). The ranking is more complicated for compressive loading as the failure mechanism may vary, but the general formula is (modulus)^n/density, where $n = \frac{1}{2}$ or $\frac{1}{3}$. While the value of the modulus can be less important because of the fractional exponent, the density always is factored to the first power. The common engineering metals cannot match, on the basis of specific modulus and strength, the decrease in structural weight that can be achieved with these ceramic materials.

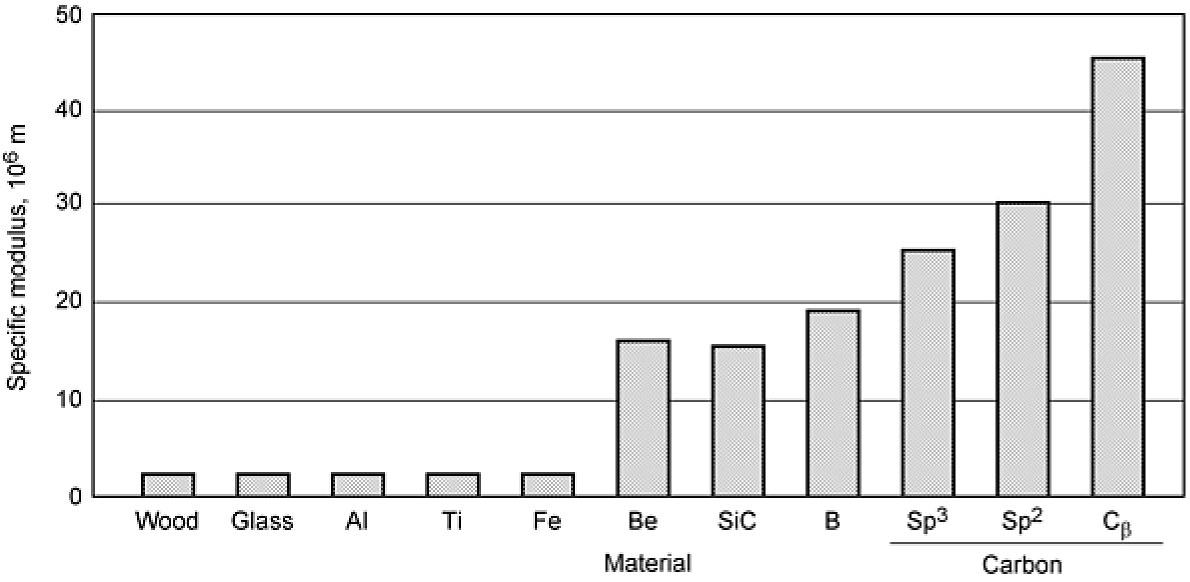

Fig. 1 Specific modulus (modulus/density) of selected materials for structural applications. Note the constancy of the common engineering metals and the high values for low-density ceramics. Source: Ref 1

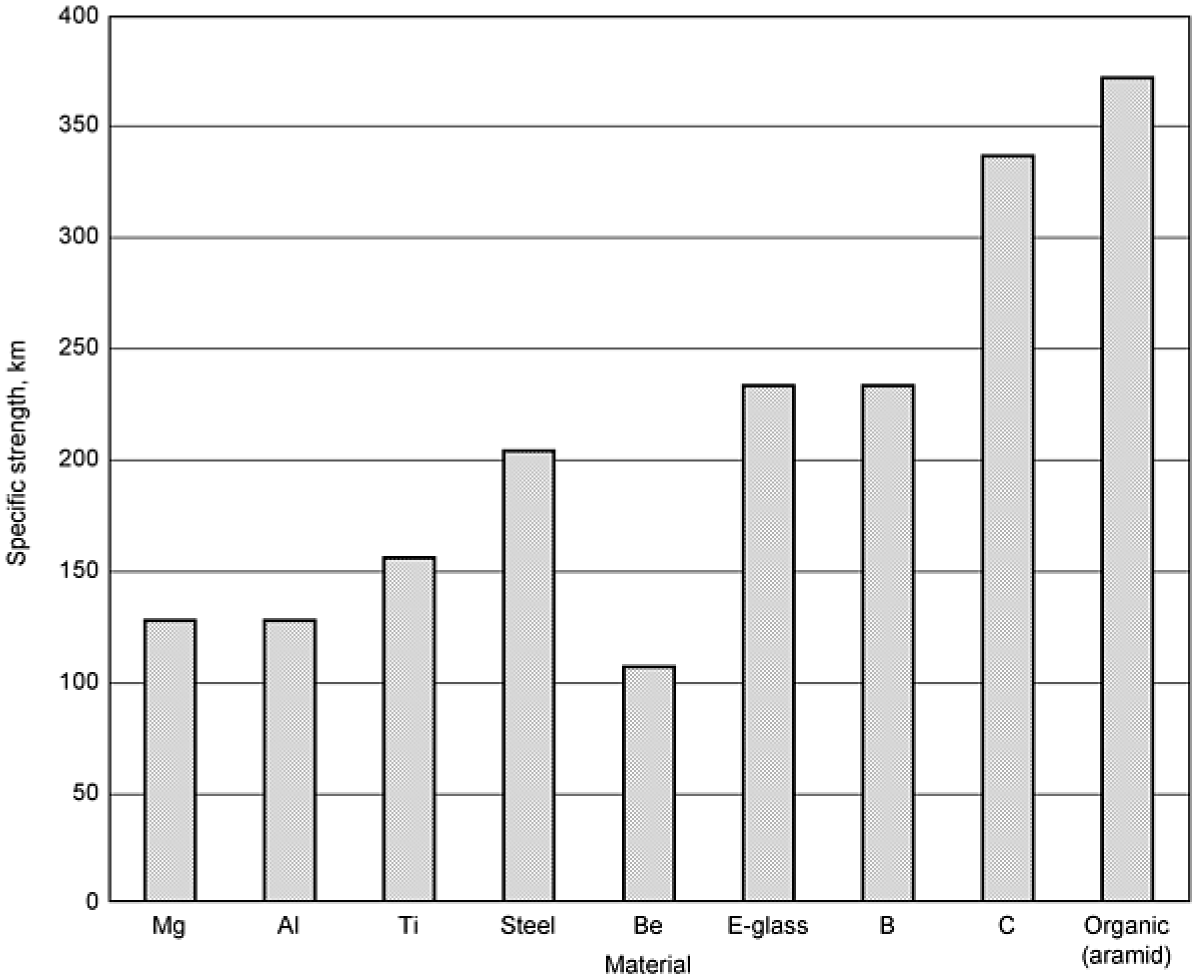

Fig. 2 Specific strength (strength/density) of selected materials for structural applications. Values are for high-strength wires. Materials with high specific moduli are often observed to have high specific strength also. Source: Ref 1

A high specific modulus and strength is insufficient to be a useful engineering material. Designers resist using brittle materials, because of poor impact, little damage tolerance, and difficulties with machining and assembly that may raise local stresses to high values. Structural integrity often depends on withstanding these high local stresses. Ductile metals yield and redistribute the stress, but composite materials exhibit a lower ductility. Stress analysis is often very good at the global scale, but is apt to be poorer in localized areas. The application of finite element analysis has decreased problems with stress concentrations, but providing the ceramic material with a pseudoductile behavior would be a breakthrough. Fiber-reinforced composite materials can provide better impact resistance and a more "graceful failure," or more yielding strain before failure. Additional information about performance characteristics of brittle materials is provided in the article "Design with Brittle Materials" in this Volume.

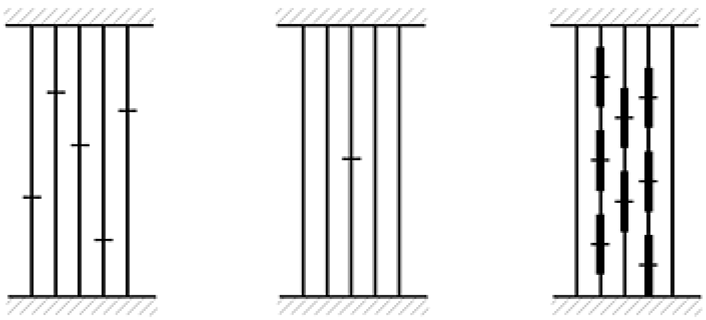
Fiber-Reinforced Composite Materials

Fibers can be made in small diameter with desirable microstructures, such that very high strength can be obtained. High loads can be carried by using a plurality of these high-strength fibers. Damage tolerance is also achieved, as the loss of a few fibers does not decrease the overall load-bearing capability much. However, if there is no coupling among a bundle of parallel fibers, fiber fractures accumulate with increasing load until the remaining fibers fail ("bundle strength") (Ref 2) (Fig. 3a). There are two problems: (1) no load is carried by a broken or discontinuous fiber, and (2) fibers buckle at very low loads in compression because of their small diameter. Man learned many centuries ago that twisting the continuous fiber bundle into a yarn provides a frictional force among the fibers that also allows discontinuous fibers to be used. Multiple breaks in a single fiber could even be generated in a yarn during loading. However, improving the compressive strength requires better fiber stabilization than coupling by friction. The problem is that in a strongly coupled system, failure of the whole structure occurs when the first fiber fails--a very low strength (Fig. 3b.). Noncatastrophic failure requires that the bond strength between the fiber and matrix be sufficiently low that when the fiber fractures, the fiber debonds from the matrix to arrest crack propagation by blunting (Fig. 3c). Damage tolerance is provided by the redundancy in load-carrying members. Localized impact may fracture a few fibers, but the load carried by the fractured fibers will be transferred through the matrix to the remaining fibers.



(a) (b) (c)

Fig. 3 Interfacial bonding. A bundle of fibers (a) usually will have about 70 to 80% of the average tensile strength determined on a single fibers. With a very strong bond between fiber and matrix (b), the whole composite will fail in a brittle manner when the very weakest fiber in the composite fails. Tensile strength is low. An optimal interfacial strength (c) will produce multiple fractures in each filament, and the tensile strength will equal or even exceed the average fiber tensile strength. Source: Ref 3

The whole basis for fiber-reinforced composites is that some of the potential strength and modulus are traded for a measure of damage tolerance and a more graceful failure. The penalty is that the strength transverse to the fiber bundle is low. The strength and modulus of a uniaxial fiber-reinforced composite is high in only one direction. Of course, fibers could be oriented in different directions to provide the required stiffness and strengths, but space is not necessarily filled very efficiently. Woven fabrics often are used to replace uniaxial plies or are added locally to improve transverse properties. For triaxially stressed parts, composites usually do not offer improved performance compared to the engineering metals. (There are important applications in which the engineering metals cannot be used, and composites are attractive.) Fortunately, structural elements are usually stressed predominantly in one (beams) or two directions (plates), and not three directions. For uniaxially and biaxially stressed elements, the performance levels possible with composites cannot be matched by other materials.

Structure / Property Relationships

A structure can be analyzed from the scale of atoms, unit cells, point and line defects, optical microstructure, beams and plates to the final level of the total structure. The dividing line between the interests of the materials engineer and the structural engineer has traditionally been between the microstructure, and beams and plates. Generally, the structural engineer was provided with a set of properties for the materials that were isotropic and homogeneous. The details of (micro)structure that determine the properties were invisible at the level of the structural engineer. Exceptions to assuming isotropy were made for metals and polymers with strong textures, and properties were provided for the different orientations. However, with composite materials, the structural engineer becomes much more the designer of the material. A composite is a structure in itself. In this case, the engineer must orient the fibers in the matrix to provide the stiffness and carry the loads. The fiber and polymer, metal, or ceramic matrix constituents are generally treated as homogeneous and isotropic, but sometimes as anisotropic.

Conceptual Design of a Composite Part. A composite part can be visualized as a group of ropes loosely coupled together by a matrix, or one step up the resolution scale as an anisotropic but homogeneous material in a beam or plate. The approach of the designer is quite different. For the rope analogy in tension, the designer attempts to have the ropes carry most of the load, while minimizing the loads carried by the matrix. By contrast, the stresses in the individual fiber and matrix constituents are not resolved in an anisotropic plate model, and the material can be treated much as a common engineering metal. (The term "black aluminum" is often used to describe carbon fiber/epoxy-matrix composites.) The design of composite materials is simplified by this approach, and much of the potential improvement in structural performance can often be achieved. Because composite laminates are frequently laid up against the surface of a mold, the fibers will follow the contour of the mold and provide high in-plane strength and stiffness. However, maximum performance is not attained, and high matrix or fiber stresses in localized regions may cause failure. The resolution of the individual constituents in a composite provides the designer with many more degrees of freedom, but more complexity.

Twist, Bend, and Splay Orientations. Fiber-reinforced laminates are usually produced by stacking a prescribed number of lamina or plies. Each ply is generally made up of uniaxially oriented fibers or woven fabric. The laminate is then built up by stacking plies at various rotations based on the predicted load state (Fig. 4). The result is much like plywood, although plies at angles other than 0/90° are also used. There are some advantages to using splay and bend fiber geometry to pick up off-axis loads (Ref 4). (Off-axis plies in Cartesian coordinates transform to logarithmic spirals for cylindrical coordinates.) Design and manufacture become more complicated, but machinery is now available to "steer" the fiber in these more complex patterns. Figure 5 shows an example of a pin-loaded joint. Not only is the stress concentration reduced at the hole, but also the maximum stress is moved from the free edge for the ply rotation case (Fig. 5b) toward the interior for bend/splay (Fig. 5c).

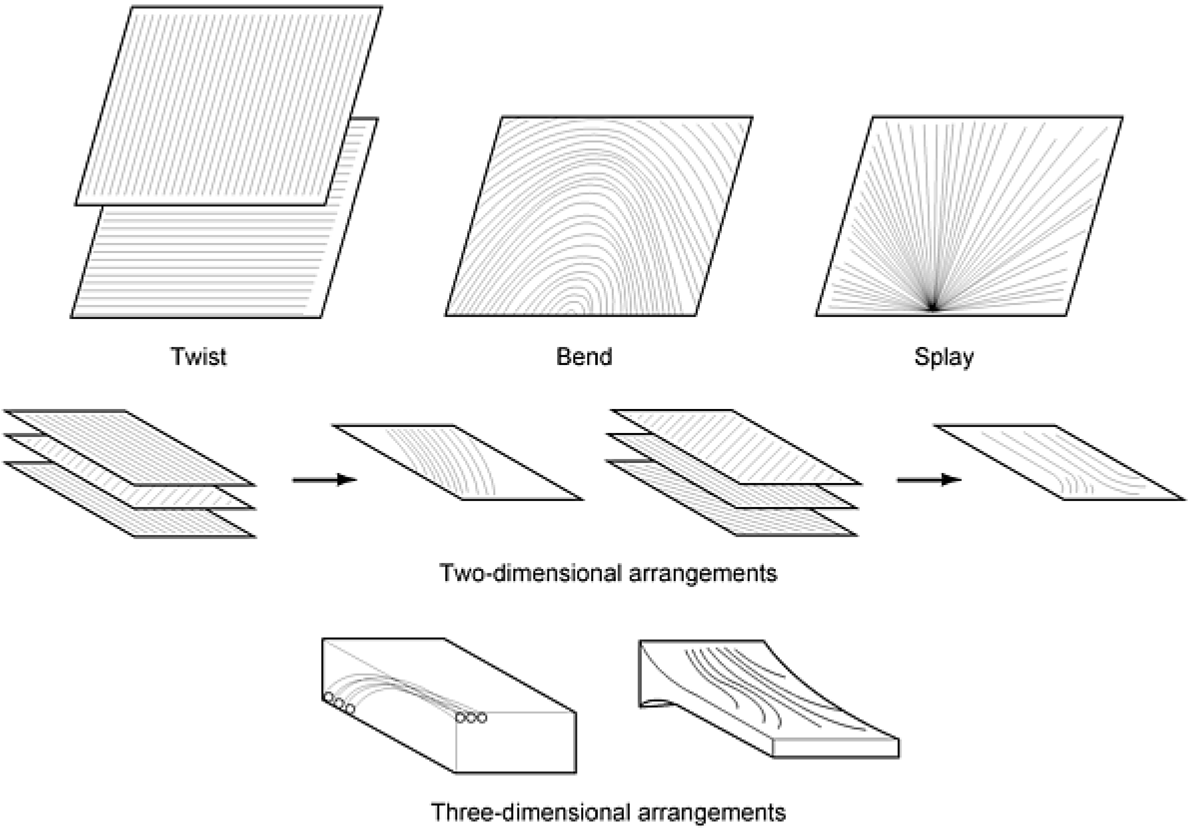

Fig. 4 Fiber arrangements. Composite laminates are generally fabricated by rotating lamina axes as shown by the twist example on the left. However, loads that are off-fiber axes cause large inter- and intralaminar matrix stresses. Safer structures can often be designed by using curved or splayed fiber paths to try to keep loads within the fibers as shown on the right. The design freedom that is added by using twist, bend, and splay is illustrated in the two- and three-dimensional design concepts. Fabric also can be used.

Generic Composite Behavior

The stress/strain and fracture behavior of uniaxial fiber-reinforced composites depends on the moduli and strains to failure of the constituents, the coupling between fiber and matrix, the residual stresses in the composite, and the loading directions. Generally, the modulus of the fiber is high, but the modulus of the matrix can vary from low to values even higher than that for the fiber.

In the case of resin-matrix composites, the fiber modulus can be 50 to even 100 times greater than that of the matrix. However, even though the strength of the fibers is usually very high, the strain to failure of the fibers (<2%) is frequently less than for the matrix. When loaded in uniaxial tension parallel to the fiber axis, the fibers carry most of the load

because of their higher modulus. The weakest fibers start to fail as the load is increased, until a large crack forms that propagates through the composite.

If the fibers and matrix are well coupled, failure can even occur when the weakest fiber fails, and the fracture surface will be relatively flat and have the classic mirror/hackle appearance (Fig. 3b). For weaker coupling, fiber failures will accumulate until a few neighboring failed fibers generate a large enough stress concentration that catastrophic failure occurs through the remaining section of the composite (Ref 5). The composite strength will be much higher than in the first case, and damage tolerance will be improved but still poor. Still lower coupling will cause less overstress from broken fiber ends on neighboring fibers, such that in the limit, failure might be conceived of as occurring when the total cross section, minus the broken fibers, can no longer support the increasing load (Fig. 3c.). Normally, this extreme is not used in composites as the tensile strength is lower, and more importantly, the off-fiber axis properties are necessarily much lower because of the poor coupling. The composite fracture surface will appear very fibrous with broken fibers projecting out from the surface to lengths of 20 diameters or more.

The strength goes through a maximum as the coupling between fibers and matrix is increased, and the fracture behavior becomes more brittle (Fig. 6). The length of the fibers projecting from the fracture surface at the maximum tensile strength is in the range of six to ten fiber diameters. The length of the projecting fibers indicates the length of fiber required to reach the breaking stress in the fiber. So, while a long fiber pullout provides toughness, a longer distance is also required to transfer stress into the fiber. In general, the fiber/matrix coupling has not been adjusted to tailor the properties of the composite toward toughness or transfer length. Polymer-matrix composites are usually optimized close to the maximum strength, which results in rather brittle systems. However, the development of ceramic-matrix composites has focused on toughness by manipulating fiber/matrix coupling.

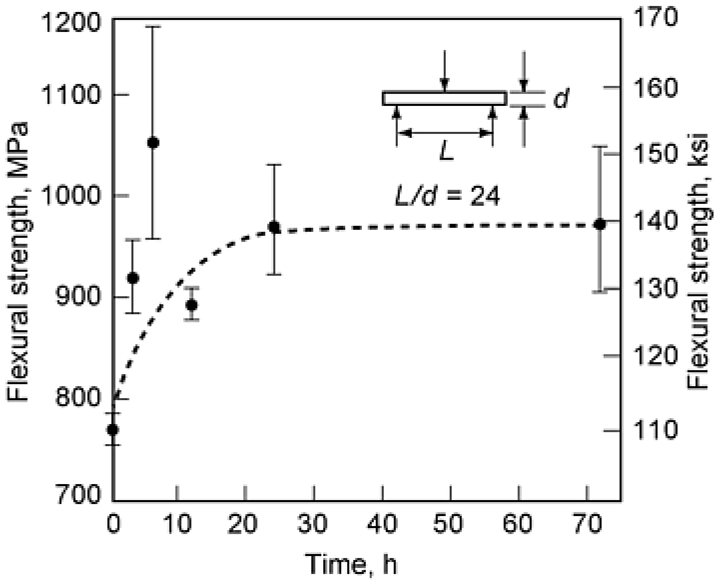

Fig. 6 Effect of interfacial bonding on strength. The coupling between fiber and matrix can be increased by the time that carbon fibers are etched in nitric acid. This first published data that bend or tensile strength has a maximum with respect to increasing interlaminar shear strength has been corroborated by other research, although the authors did not draw the curve to indicate a maximum. The bend strength is initially low, when the interlaminar shear strength is also low. The fracture surface, after the maximum, often has an identifiable brittle mirror/hackle pattern, because of too high an interfacial bond strength. The highest strengths in this brittle region can be higher than for poorer bonding, but the scatter also increases such that the average strength decreases. Source: Ref 6

Compressive strength of uniaxially oriented composites, loaded parallel to the fiber axis, is determined partly by the support provided by the matrix and neighboring fibers. Higher modulus matrices and tighter coupling between fiber and matrix can improve compressive strength (Ref 7). The overall fiber buckling load is proportional to the fiber modulus and diameter, but carbon and organic fibers buckle internally (Ref 8). In higher-modulus carbon or organic fibers, the compressive strength is a fraction of the tensile strength, which is design limiting for many applications.

The weak coupling between fiber and matrix, which is necessary to control fracture behavior when the composite is loaded parallel to the fiber axis, decreases off-axis and transverse tensile strength drastically. Any significant off-axis or transverse tensile loads require fibers to be oriented to pick up the loads. Fibers really are "reinforcing fibers" in low-modulus matrices.

Fibers and matrices can be combined in countless different ply orientations and sequences in composite materials. The cost to characterize the properties even at room temperature much less at high temperature would be prohibitive. Analytical procedures are required to calculate the properties, ideally from the properties of the constituent materials, and then validate the predictions by selected experiments (Ref 9). Unfortunately, the magnitude of the coupling between the fiber and matrix is often unknown, and the variable packing of the fibers is generally not accounted for. Calculations of composite properties from the constituent properties of the fiber and matrix have not always been successful. Progress is being made in the methodology and particularly in computational speed. The fracture behavior should be directly calculable for even composites with unusual fiber trajectories by the turn of the century. The short-term solution has been to determine the lamina properties experimentally and to calculate laminate properties from lamina. A number of computer programs for calculation of laminate properties for resin-matrix composites are available. Even the programs for personal computers provide a good first cut for most resin-matrix composite properties. Extensive experimental determination of the properties of many polymer- and carbon-matrix composite laminates has also been performed, and data are available in U.S. National Aeronautics and Space Administration (NASA) and Department of Defense (DoD) publications, including *MIL-HDBK-17.* Data for metal-matrix composites are less abundant, but still voluminous. Both metal- and ceramic-matrix composite data are much more scattered, and the values are frequently process and producer dependent. Additional information is provided in the article "Sources of Materials Properties Data and Information" in this Volume.

Design with Composites

R.J. Diefendorf, Clemson University

Lamina Properties

Fiber-reinforced composites have higher performance if the fibers are continuous, with the only fiber cuts occurring at the ends of the parts or subparts. While the geometrical lay-up of these fibers could be in any complex pattern, a local orientation of parallel fibers, such as a uniaxial tow or lamina, provides a high packing density. The lamina is the basic structural unit of many composites, as it is available in a form readily fabricated into sheet, tubes, or more complex shapes. Off-axis properties can be improved by including lamina with different orientations within the composite or by interleafing fabric into the lamina. Given the importance of lamina properties, but the large number of fibers and resin matrices, it is helpful to calculate lamina properties from the matrix and fiber constituent properties. Detailed information about the manufacture of composites is provided in the article "Design for Composite Manufacture" in this Volume.

Constituent Properties

The properties of carbon and other fibers are not changed when they are fabricated into a resin-matrix composite. Similarly, the resin properties do not appear to be much different in a composite than from a cured specimen of neat resin (resin with no fiber included), although there are notable exceptions. Hence, while the properties of thermosetting resin certainly change during cure, the final cured-state properties are often not affected by the presence of fibers. The system constituents are largely noninteracting, although fiber coupling agents can change properties. In general, though, constituent properties can be determined independently and used for any lamina calculation.

High-temperature composites are used and usually processed at high temperature, which may alter the constituent properties. For example, heating a carbon fiber to a temperature higher than the processing temperature of the fiber usually increases the fiber modulus and thermal conductivity, but decreases the strength, the strain to failure, and the coefficient of thermal expansion. If the constituents are noninteracting, the new properties can be determined after the appropriate heat treatment.

Constituents do interact chemically or mechanically in many high-temperature composite systems. The matrix may chemically attack the fiber surface to form a new compound, or may dissolve it. The attack is usually not very uniform, and the strength of the fiber is often degraded. Even in systems that are predicted to be thermodynamically stable, the matrix may dissolve and reprecipitate the fiber phase. There is always the same volume fraction of the fiber phase, but the microstructure is usually coarsening to minimize surface area. A number of studies in the past have measured the strength of the degraded fiber after etching away the matrix, and then these values were used for calculations to compare to experimental values. However, a poor composite strength value may be an indication of either fiber degradation, or too strong an interfacial coupling between fiber and matrix. The cause can be determined by scanning electron microscope observation of the fracture and fiber surfaces. Because of these difficulties, composite properties are often calculated from the original fiber strength to serve as an upper-limit benchmark. The observed strength can be compared to this benchmark to determine how effective the processing is.

Mechanical interactions during processing can often affect properties. For example, fibers inhibit sintering of a ceramic powder compact by restraining matrix shrinkage. An especially important example is carbon/carbon. The matrix often orients on the fiber surface and elongates during processing. The fiber is stretched when the matrix elongates, and the texture and modulus of the fiber increase. The increase in modulus is much greater than a simple heat treatment of the bare fibers. In contrast, some matrices do not wet the fibers and ball up. Because carbon fibers are not easily extracted from the carbon matrix, mechanical testing can often not be performed, and the fiber and matrix properties are determined by an inverse calculation from composite data. However, a single carbon fiber with a carbon-matrix coating can be tested.

Calculation of Lamina Properties

The modulus, strength, and coefficient of thermal expansion of matrices, and fibers parallel to the fiber axis can be measured relatively easily, but the fiber properties transverse to fiber axis are either difficult to measure or not measurable. Many fibers are isotropic, so that transverse properties are the same as the axial. However, carbon and organic fibers are extremely anisotropic. Some pitch precursor carbon fibers are even transversely anisotropic, for example, the transverse properties vary with direction. These transverse properties are not known very well for many carbon and organic fibers.

Parallel Properties. Estimates of modulus, strength, and coefficient of thermal expansion can be quickly made from a parallel model "rule-of-mixtures" type of calculation (Ref 10, 11, 12). Hence:

$$E_C = E_F V_F + E_M(1 - V_F) \qquad \textbf{(Eq 1)}$$

$$\sigma_C = \sigma_F V_F + \sigma_M(1 - V_F) \qquad \textbf{(Eq 2)}$$

$$\alpha_C = (\alpha_F E_F V_F + \alpha_M E_M V_M)/E_C \qquad \textbf{(Eq 3)}$$

where E is modulus, V is volume fraction, σ is strength, and α is coefficient of thermal expansion of the composite (C), fiber (F), and matrix (M).

The modulus estimate is exact for fibers and matrix that have the same Poisson's ratio, which for brittle fibers and matrices tends to be true. (The modulus of the composite may be about 5% higher than calculated by rule of mixtures, for

ductile-matrix composites.) Although the derivation assumes isotropic constituents, the thermal expansion coefficient estimate is also in good agreement with experimental results, even for the case of anisotropic fibers.

The observed tensile strength is often close to the rule of mixtures estimate for a good "composite," although there is no fundamental argument that the estimate will always be close to the experimental value. However, if the interfacial coupling between the fiber and matrix is optimal, the stress concentration, produced by a broken fiber upon neighboring fibers, is offset by the higher strength of a fiber at short gage lengths. Strengths measured at 2 mm, which is still longer than the overstressed region next to a broken fiber in the composite, are usually significantly stronger than that at 25 mm gage length (a normal test length).

The compressive strength of composites loaded parallel to the fibers has been predicted by a number of models. Instability analysis of fibers supported in a medium with composite properties and a moderate-to-higher volume fraction of fibers (neighboring fibers buckle in-phase) results in (Ref 13):

$$\sigma_C = G_B/(1-V_F) \qquad \textbf{(Eq 4)}$$

where σ_C is the longitudinal strength of the composite in compression, G_B is the shear modulus of the binder that is composed of matrix and fiber (a lower-limit estimate would be the shear strength of the matrix), and V_F is the volume fraction of fibers.

The values predicted by this equation tend to be higher than the experimental strengths. However, for composites with very well aligned large-diameter fibers, homogeneously distributed, for example, a well-made boron filament composite, the observed strengths are only somewhat lower than predicted. The effects of binder yielding, and fiber misalignment have been used to formulate models that predict the experimental compressive strength better for some composites (Ref 14). The difficulty is determining which particular model should be applied. In general, the compressive strength for fine-diameter fibers is often observed to be similar to the tensile strength.

Two important classes of fibers produce very low compressive strengths because of internal fiber buckling. High-modulus organic fibers that have axially oriented linear molecules, and higher-modulus carbon fibers that have a molecular sheetlike structure oriented parallel to the fiber axis, fail by molecular buckling at low stresses. While the magnitude of stress for internal buckling can be predicted, coupling of the molecules by atomic bonding or microstructurally will alter the buckling stress. Unfortunately, experimental compressive strengths, reported in the literature, show much scatter. Testing is difficult and is very sensitive to specimen quality.

A number of other models have also been derived to more precisely describe composite properties. One that is useful for easy estimates of properties from isotropic constituents, because of its closed form, is the composite cylinder assemblage (CCA) model (Ref 15):

$$E_{CL} = E_{av} + 4V_FV_M(\nu_F - \nu_M)/(V_M/k_F + V_F/k_M + 1/G_M) \qquad \textbf{(Eq 5)}$$

where E_{CL} is the longitudinal composite modulus; E_{av} is the volume-averaged modulus of the two phases (ROM average); $V_{F,M}$ is the volume fraction of the fiber and matrix, respectively; $\nu_{F,M}$ is the Poisson's ratio of the fiber and matrix, respectively; $k_{F,M}$ is the bulk modulus of the fiber and matrix, respectively; and G_M is the shear modulus of the matrix.

Similarly, the longitudinal composite Poisson's ratio (ν_{CL}), and shear modulus (G_{CL}) are:

$$\nu_{CL} = \nu_{av} + V_FV_M (\nu_F - \nu_M) (1/k_M - 1/k_F) / (V_M/k_F + V_F/k_M + 1/G_M) \qquad \textbf{(Eq 6)}$$

$$G_{CL} = G_M[V_MG_M + (1 + V_F)G_F] / [(1 + V_F)G_M + V_MG_M] \qquad \textbf{(Eq 7)}$$

where ν_{av} is the volume averaged Poisson's ratio for the fiber and matrix, G_F is the shear modulus of the fiber, and the other terms are as previously defined. These estimates of the longitudinal composite properties are all quite accurate.

Transverse properties depend on the constituent properties, the volume fractions, and the packing. The properties of carbon and organic fibers are anisotropic, and often the transverse properties are not well known, if at all. In fact,

experimental values of the transverse properties are used to perform the inverse calculation for obtaining fiber properties. The calculation can be performed assuming anisotropic constituents (Ref 9), and while small errors may be introduced from fiber-packing assumptions, these errors are canceled out when the same values are used for calculating composite properties. The transverse elastic properties can be estimated for isotropic constituents by the CCA model (Ref 15):

$$E_{CT} = 4k_{CT}G_{CT}/[k_{CT} + E_{CL}G_{CT}(1 + 4k_{CT}\nu^2_{CL})] \quad \textbf{(Eq 8)}$$

$$\nu_{CT} = \frac{1}{2}(E_{CT}/G_{CT}) - 1 \quad \textbf{(Eq 9)}$$

where:

$$k_{CT} = (k_M k_F + k_{av}G_M)/(V_M k_F + V_F k_M + G_M)$$

$$G_{CT} = G_M[(\alpha + \beta_M V_F)(1 + \rho V^3_F) - V_F V^2_M \beta^2_M]/[(\alpha - V_F)(1 + \rho V^3_F) - 3V_F V^2_M \beta^2_M]$$

and:

$$\alpha = (\gamma + \beta_M)/(\gamma - 1)$$
$$\beta = 1/(3 - 4\nu)$$
$$\rho = (\beta_M - \gamma\beta_F)/(1 + \gamma\beta_F)$$
$$\gamma = G_F/G_M$$

The transverse thermal expansion coefficient can also be estimated:

$$\alpha_{CT} = \alpha_{av} + [(\alpha_M - \alpha_F)/(1/k_M - 1/k_F)]\,[3/(2k_{CT}) - (3\nu_{CL}(1 - 2\nu_{CL}))/E_{CL} - (1/k)_{av}] \quad \textbf{(Eq 10)}$$

where α_{av} is the volume average of the fiber and matrix thermal expansion coefficients and $(1/k)_{av}$ is the volume average of the reciprocal of the fiber and matrix bulk moduli.

Shear and Transverse Strength of a Uniaxial Resin-Matrix Composite. The two principal directions of applied shear stress are in a plane that contains the filaments and in a plane normal to the filaments. The shear strength for the first case is determined mainly by the shear strength of the matrix, the fiber/matrix interface, and the longitudinal shear strength of the fiber, while the second may have substantial reinforcement from the fibers. Generally, the matrix or interfacial strengths are the weak links, but in a few cases fiber shear failures have been observed. For resin-matrix composites, the shear strength for in-plane shear is typically equal to the shear strength of the resin. Similarly, the transverse tensile strength for resin-matrix composites is usually about one-half the tensile strength or equal to the shear strength of the resin. For off-fiber axis loading, the weak coupling between fiber and matrix--required to control axial fracture--causes the shear and transverse tensile strength to always be low, even with high-strength matrices and fibers.

Shear stresses are present within and between lamina, a distinction that is frequently not made. Care should be made in selecting stacking sequences of lamina, such that lower interlaminar shear stresses are generated at free edges and elsewhere.

Residual stresses usually result when lamina are used at temperatures that differ from the fabrication temperature because of the difference in the thermal expansion coefficients of the fiber and matrix. Warping occurs in curved laminates. However, residual stresses also exist in unwarped structures that have no net bending or twisting moments. Cracking can occur in the constituents, and thermal fatigue from thermal cycling has been observed in metal-matrix composites.

Processing residual stresses are due to the volume change that occurs upon curing of a resin, or within a chemically vapor deposited matrix. The volume change will cause stresses, which may not be annealed out at the processing temperature. The general conclusion is that a composite cannot be assumed to be stress-free before use.

General Lamina Properties

The elastic properties of a lamina in any in-plane direction can be calculated from the above mechanical properties measured in the principal materials directions by simple tensor transformations (Ref 16). The Young's modulus, shear modulus, Poisson's ratio, and the major shear coupling constant are shown in Fig. 7 for glass and boron/epoxy composites (Ref 12). The figure contrasts the behavior of a lower and higher modulus reinforcement. (E_X and G_{XY} are normalized by E_{CT} and G_{LT} to allow convenient plotting of the properties.) Both plots show the rapid drop-off in Young's modulus as the applied load is rotated away from the fiber axis of the composite because of the low matrix shear modulus. Interestingly, the lowest modulus for the boron fiber/epoxy resin composite is not at 0 or 90°, but at about 50°. Similarly, a maximum in Poisson's ratio occurs at about 25° for both composites. As might be expected from composite geometry, the shear modulus shows a maximum at 45°.

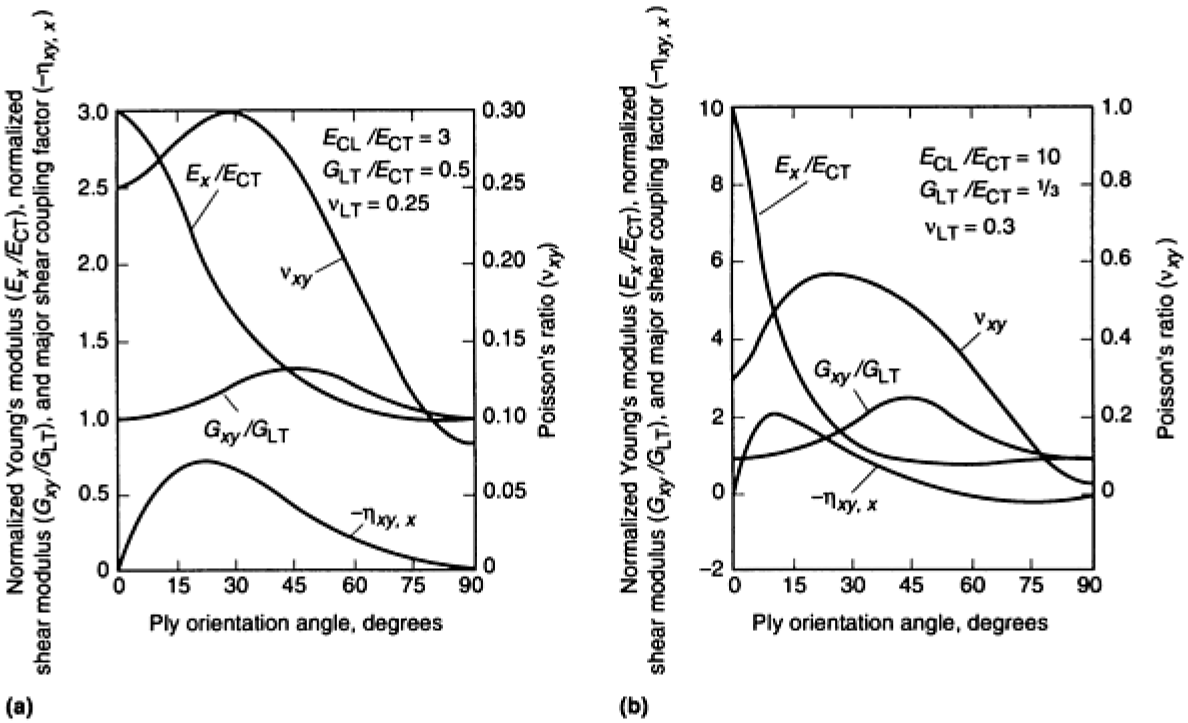

Fig. 7 Normalized moduli versus fiber orientation for a glass-fiber/epoxy-resin composite (a) and a boron-fiber/epoxy-resin composite (b). The normalized Young's modulus, shear modulus, Poissons' ratio, and major shear coupling factor are illustrated for loads applied at different angles with respect to the fiber orientation. 0°, load is applied parallel to the fiber axis; 90°, fiber oriented transverse to the load direction. Source: Ref 17

Lamina require an extra elastic constant, the major shear coupling factor, that relates the applied load to the in-plane shear deformation. The magnitude of the constant also provides an indication of the rotation of the fiber axis that occurs because of the shear deformation. There is no shear deformation when the load is applied parallel (0) or transverse (90) to the fiber axis. However, when the load is applied at any other angle in the glass-fiber composite, a shear deformation is induced, and the fibers rotate to become more parallel to the tensile load. Both composites show a maximum near 15°. For higher-modulus fibers, the sign of the factor reverses for high angles of loading, and the fiber rotation is toward a transverse orientation with respect to load. Hence, there are three angles for higher-modulus resin-matrix composites for which there is no shear deformation. These are 0, 90, and about 60° for boron-fiber/epoxy-matrix composites. Selection of lamina angles that have small major shear coupling factors minimizes shear stresses, especially at free edges.

For example, a $(+15/-15)_S$ composite is found to meet load and deflection requirements at a minimum weight; the subscript "S" indicates a symmetric (+15/-15/-15/+15) laminate. However, the large shear deformations that occur in each ply cause large interlaminar shear stresses at the free edge of the part, and may cause delamination. A $(0/+45/-45)_S$ composite might not be so structurally efficient, but the laminate has zero or small major shear coupling factors.

The strength of a lamina also varies with respect to the loading direction and the fiber axis. Failure, predicted by a maximum stress theory, occurs when any one of the stress components resolved to the material axes exceeds (Ref 18):

$$\begin{aligned} &\sigma_{LT} > X_{LT} \text{ or } \sigma_{LC} > X_{LC} \\ &\sigma_{TT} > X_{TT} \quad \sigma_{TC} > X_{TC} \\ &\sigma_{S} > X_{S} \end{aligned} \quad \textbf{(Eq 11)}$$

where X_{LT} is the tensile strength in the fiber direction, X_{TT} is the tensile strength transverse to the fibers, and X_S is the shear strength.

The strengths in compression, which are not generally the same as in tension, are indicated by the added subscript "C." A high tensile strength, fiber-dominated mode, is observed when a tensile load is applied nearly parallel to the fiber (Fig. 8). Failure shifts to a shear mode, usually in the matrix or at the fiber/matrix interface, as the load is applied more obliquely. Finally, failure occurs by transverse tension. For polymer-matrix composites, there is significant overprediction of tensile strength compared to the experimental values, especially near zero and 45°. A maximum strain criterion for failure has also been used, but with similar disagreement with experiment. Both sets of criteria neglect the interaction of failure modes.

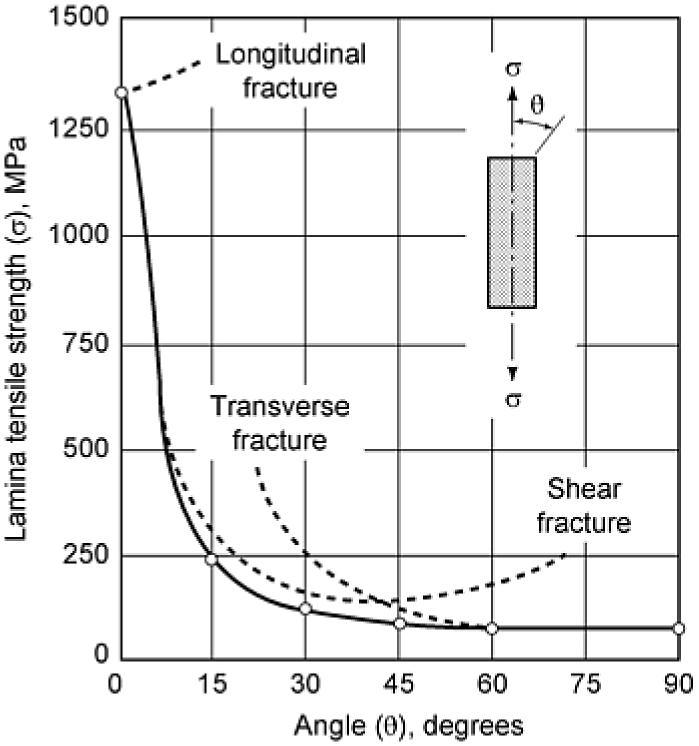

Fig. 8 Uniaxial lamina strength versus fiber orientation. The fracture stress curves, using the maximum stress criteria, are indicated by the dashed lines for a boron-fiber/epoxy-matrix composite. A fracture curve using a quadratic interaction criterion is shown with the solid line. Experimental points are indicated by open circles. Source: Ref 19

Better failure models have been suggested, but they require more data points, particularly from biaxial tests (Ref 18). When the failure is complex, the value of the expression for the curve becomes less valuable, if a large number of data points are required to define it.

Discontinuous Fiber Lamina

Long discontinuous fibers offer some processing advantages with little penalty in axial properties. Variations on papermaking and other processes have been used to produce well-oriented fiber lamina, which can be impregnated with a

metal, ceramic, or polymer. The initial work was performed on fine whiskers and later on carbon and aramid fibers. Mechanical tests show only a modest 10% loss in axial modulus, and a 15% loss in tensile strength in uniaxial composites (Ref 20). Shear and transverse properties were increased by as much as a factor of two, because of a substantial contribution from off-axis fibers.

The discontinuous fibers allow large deformations in a prepreg or a thermoplastic laminate, such that more complex parts can be directly molded to shape. Studies have been performed and computer programs developed that predict the proper movement of the fibers to occur during processing, such that a high-performance part can be achieved. There is much that is attractive, but chopping a continuous fiber and then reforming it to a discontinuous oriented composite has probably limited its application. However, there is significant use of chopped-fiber/resin composites for lower-cost, lower-performance applications.

Laminate Properties

Composite laminates are constructed from lamina with uniaxial fiber orientation and frequently from textile fabrics as well. The choice of fiber and matrix, ply orientation, and thickness is made to match the required loads and deflections. The extensional stiffness of the laminate is simply the sum of the individual laminate stiffnesses for the defined direction multiplied by the lamina thickness. The deformation of the composite can be quite complex with twisting, bending, or in-plane shearing occurring as well as simple extension under a tensile load. While twisting or bending for most applications would be undesirable, there are special cases where this behavior is beneficial. A conceptual approach to the types of deformation is discussed with respect to symmetries for in-plane and through-thickness loading directions (Fig. 9).

Symmetric laminate (0°/90°/0°)$_T$

$$\begin{bmatrix} N \\ N \\ N \end{bmatrix} = \begin{bmatrix} A & A & 0 \\ A & A & 0 \\ 0 & 0 & A \end{bmatrix} \begin{bmatrix} \varepsilon \\ \varepsilon \\ \varepsilon \end{bmatrix}$$

$$\begin{bmatrix} M \\ M \\ M \end{bmatrix} = \begin{bmatrix} D & D & 0 \\ D & D & 0 \\ 0 & 0 & D \end{bmatrix} \begin{bmatrix} k \\ k \\ k \end{bmatrix}$$

Unsymmetric cross ply (0°/90°)$_T$

$$\begin{bmatrix} N \\ N \\ N \end{bmatrix} = \begin{bmatrix} A & A & 0 \\ A & A & 0 \\ 0 & 0 & A \end{bmatrix} \begin{bmatrix} \varepsilon \\ \varepsilon \\ \varepsilon \end{bmatrix} + \begin{bmatrix} B & 0 & 0 \\ 0 & B & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} k \\ k \\ k \end{bmatrix}$$

$$\begin{bmatrix} M \\ M \\ M \end{bmatrix} = \begin{bmatrix} B & 0 & 0 \\ 0 & B & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{bmatrix} \varepsilon \\ \varepsilon \\ \varepsilon \end{bmatrix} + \begin{bmatrix} D & D & 0 \\ D & D & 0 \\ 0 & 0 & D \end{bmatrix} \begin{bmatrix} k \\ k \\ k \end{bmatrix}$$

Unsymmetric angle ply (+15°–15°)$_T$

$$\begin{bmatrix} N \\ N \\ N \end{bmatrix} = \begin{bmatrix} A & A & 0 \\ A & A & 0 \\ 0 & 0 & A \end{bmatrix} \begin{bmatrix} \varepsilon \\ \varepsilon \\ \varepsilon \end{bmatrix} + \begin{bmatrix} 0 & 0 & B \\ 0 & 0 & B \\ B & B & 0 \end{bmatrix} \begin{bmatrix} k \\ k \\ k \end{bmatrix}$$

$$\begin{bmatrix} M \\ M \\ M \end{bmatrix} = \begin{bmatrix} 0 & 0 & B \\ 0 & 0 & B \\ B & B & 0 \end{bmatrix} \begin{bmatrix} \varepsilon \\ \varepsilon \\ \varepsilon \end{bmatrix} + \begin{bmatrix} D & D & 0 \\ D & D & 0 \\ 0 & 0 & D \end{bmatrix} \begin{bmatrix} k \\ k \\ k \end{bmatrix}$$

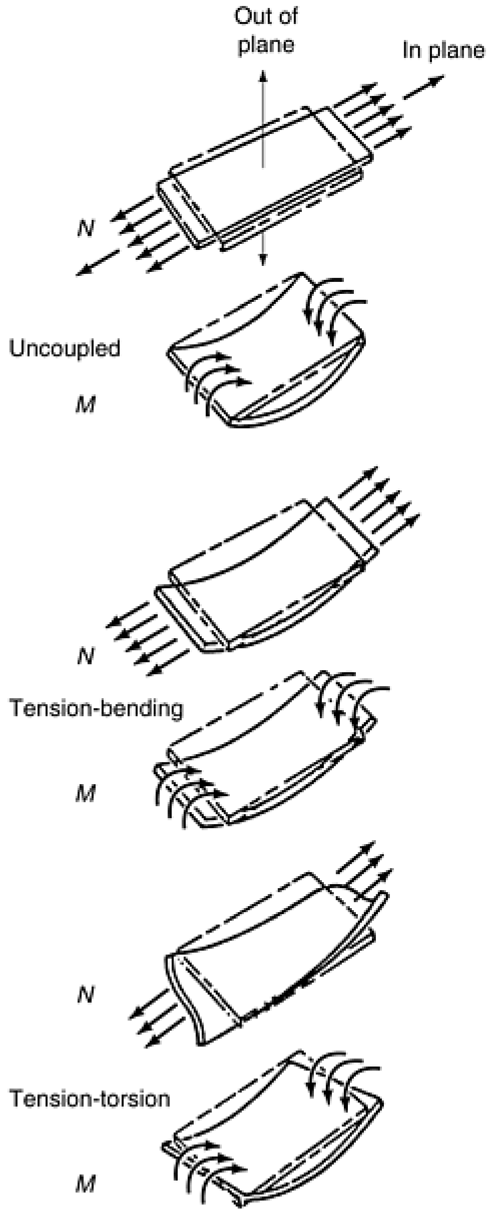

Fig. 9 Deformation behavior of composites. The deformations for composites with various symmetries are schematically illustrated for in-plane loading and bending. Generally, laminates that are symmetric through the thickness and symmetric in-plane with respect to the applied stress are used because no in-plane shear distortion or out-of-plane bending occurs. Less-symmetric laminates are useful for special applications. *N,* normal stress; *M,* bending moment. Source; Ref 21

Symmetric In-Plane and Through-Thickness Laminates

A thin laminated composite can be fabricated that is symmetric to the applied load direction by balancing in-plane ply orientations and thickness and with the plies symmetrically distributed about the mid-plane through the thickness. Hence with a load applied at zero degrees, for every ply at $+\phi$, there must be a ply at $-\phi$, and the distribution of plies about the thickness midplane must be a mirror image both in angle and distance from the midplane. A symmetric in-plane and through-thickness laminate might be $(0_4/+45_2/-45_2/90)_S$, where the subscript "S" indicates that the laminate is symmetric about the mid-plane. In this 18-ply laminate, the 0° plies are on each outside, and the 90° plies are in the center. The effect of balanced construction of plies at $\pm\phi$ instead of just $+\theta$ is quite strong (Fig. 10). The modulus for balanced ± ply construction decreases more slowly as the plies are rotated off the loading axis because of the inhibition of shear by alternate angle plies. Similarly, the shear modulus is much higher for the balanced ± composite, particularly at 45°. The Poisson's ratio effect can be positive and large ($\sim$1) for high-modulus fibers when θ is small (<30°). The large Poisson's

ratio can be used in tubular structures to give a "Chinese finger puzzle" effect, because a composite tube tightens down on a rod when a tensile load is applied.

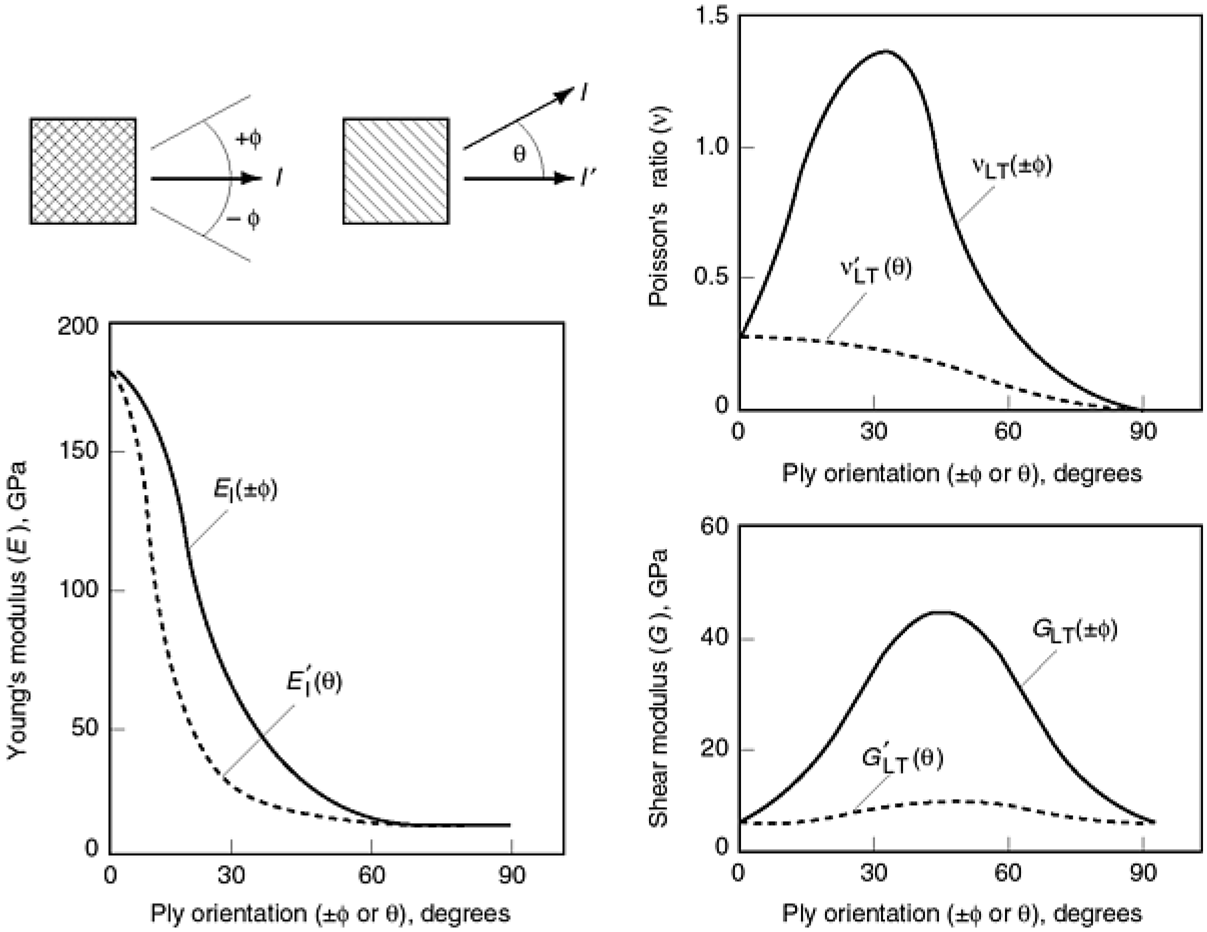

Fig. 10 Effect of balanced-angle ply construction on engineering mechanical constants. The Young's modulus and shear modulus of a laminate can be significantly higher if plies are oriented at both plus and minus an angle with respect to the stress axis rather than just at one of the directions. The very high Poisson's ratio for a balanced ply construction and small orientation angles provides a "Chinese finger puzzle" effect with a cylinder. Source: Ref 22

A tensile load applied at the 0 or 90° axis of a material results in a simple extension with no distortions in- or out-of-plane (as shown for the symmetric laminate in Fig. 9). No distortions make this "doubly" symmetrical composite desirable for many flat laminate applications. A special case is the $0_i/+45_j/-45_j/90_k$ composite laminate in a symmetric stacking sequence. The composite is isotropic in-the-plane when *i*, *j*, *k* are equal, but the numbers of 0, ±45, and 90° plies can be varied to provide optimal directional stiffness and strength. In addition to no distortions, the "scissoring" of the ±45 plies is small, which minimizes the likelihood of edge delamination.

The importance of the $0_i/+45_j/-45_j/90_k$ laminates in symmetric stacking sequences has lead to the development of a "carpet" plot that shows a property for variable *i*, *j*, *k*. The plots of composite properties for quite a few systems are available in government reports (Ref 23). While computer programs have eliminated some of the value of these plots, they provide a very easily comprehended visual input to the trends of composite properties with varying *i*, *j*, *k*. An example of a lower-modulus carbon fiber in an epoxy matrix is shown in Fig. 11. In Fig. 11(a), the tensile elastic modulus is plotted for various percentages of 0, ±45, 90° plies. The curve is read by selecting the percentage of 0° plies (which are next to the diagonal line), then picking the percentage of ±45° plies, and finally reading off the modulus from the appropriate curve. The intercepts on the modulus ordinate show how the modulus decreases as the 0° plies are replaced by 90° plies. Similarly, the intercepts on the diagonal line indicate the decrease in modulus as 0° plies are replaced by ±45° plies. Finally, the modulus would be read off one of the more horizontal curves when all three angles are present. The plot shows the example of a composite with 50% of the layers in the ±45° direction and with 25% each in the 0° and 90° directions. The general trends are easily ascertained by looking at the plot. The other part of Fig. 11 show the results for

shear modulus, Poisson's ratio, and tensile, compressive, and shear strength. Strength has to be uconsidered carefully with the application. The accumulation of fiber, matrix, and even ply failures make the decision of what is considered failure difficult. Commonly, the design ultimate stress is defined as the maximum stress that does not result in rupture of any of the lamina in the laminate. Design limit stress is the maximum stress for which no laminate damage or degradation of stiffness occurs; it is normally used as the "yield" strength of the composite.

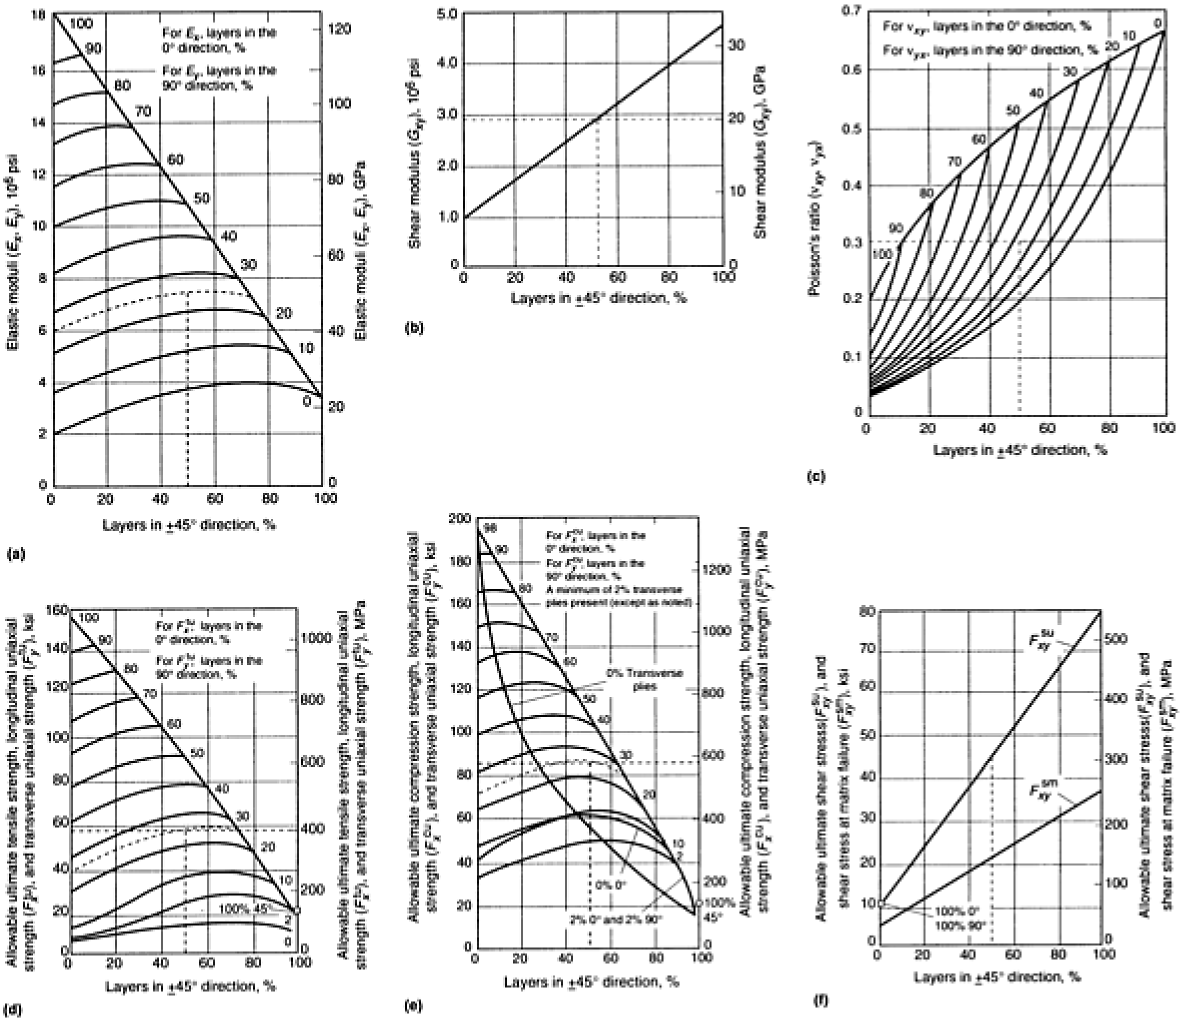

Fig. 11 Symmetric laminate properties for carbon-fiber (V_F = 65%)/epoxy-resin composites with variable percentages of plies at 0, ±45, and 90°. (a) Tensile modulus. (b) Shear moudulus. (c) Poisson's ratio (tension). (d) A-basis tensile strength. (e) A-basis compression strength. (f) A-basis shear strength. A-basis values predict 99% chance of survival with 95% confidence level. The subscripts *x* and *y* indicate the measured property in the 0° to 90° fiber orientation, respectively.

Asymmetric In-Plane and Symmetric Through-Thickness Laminates

An example of this class of composite is +15/0/+15° laminate. Tensile loading of this composite produces an in-plane shear deformation (distortion) with no out-of-plane deformation. Bending of these composites normally causes twisting as well as bending when the load is applied along the centerline of the laminate. However, there is an asymmetric loading point in bending that produces pure twist with no bending and another that produces pure bending with no twist.

Composites provide the ability to asymmetrically load a beam in bending, which results in no torsional deflection of the member. An application might be an automobile suspension for a wheel. The composite would allow the tire to remain fully in contact with the road over the full suspension travel. While this can be achieved with multilink suspensions, composites offer the possibility of very simple designs.

Design with Composites

R.J. Diefendorf, Clemson University

Asymmetric Laminates

Asymmetric laminates are a subclass of composite laminates that provide designers with a unique set of properties. Asymmetric laminates show a coupling between in-plane stresses and out-of-plane deflections that can be predicted using laminated plate theory (Fig. 9). Asymmetric laminates have an unsymmetrical stacking sequence with respect to the midplane of the laminate, and most react to mechanical stresses and to water and thermally induced (hygrothermal) stresses. Thus, laminates that are designed to twist or bend due to an in-plane load also have the potential to react to changes in temperature or humidity. This combined response to mechanical and hygrothermal stresses has been a barrier to their application (Ref 24). However, a family of asymmetric laminates has been found with mechanical tension/bending or tension/torsion coupling that is unaffected by hygrothermal changes (Ref 25). These laminates, when used as flat laminates or tubes with symmetric cross section, yield hygrothermal shape stability that was thought only possible through the use of symmetrically stacked laminates. While these laminates show no hygrothermal couple, they retain a strong mechanical coupling. Surprisingly, the solution for curvature stability is obtainable over a wide range of coupling coefficients and is independent of the thermal expansion and moisture swelling coefficients of the individual laminates.

Temperature changes warp most metal-, ceramic-, or polymer-matrix, asymmetric composites, while moisture absorption also warps many polymer-matrix asymmetric composites. Because the unsymmetrical laminates studied in the literature are prone to warping, the inductive conclusion that all unsymmetrical laminates warp is frequently stated in the literature. A solution to this problem is simply a $(0/90)_S$ symmetric laminate joined to a second laminate rotated by an angle θ. Each laminate is hygrothermally shape stable because it is symmetric and induces zero hygrothermal shear strain for all θ, and the combined laminate then is also hygrothermally shape stable. The system is not mechanically isotropic, and thus produces a tension/torsion or tension/bending coupling. The maximum value of the coupling coefficient is only reduced by about 15% from the classical $(\theta, -\theta)_T$ warping case. (The subscript "T" stands for a through-thickness stacking sequence.) Of course, temperature or moisture adsorption gradients, as may occur when only one side of the laminate is exposed, still causes warping just as with isotropic materials.

Some caution should be used when applying laminate theory to asymmetric laminates. For example, laminate theory predicts that a $(0/90)_T$ asymmetric laminate will assume a saddle shape as a result of an applied load or temperature change. In practice, the resulting shape usually is almost cylindrical. The reason for this unpredicted behavior is that the deflections are not small compared to the laminate thickness (as assumed in laminated plate theory). Better solutions have been derived (Ref 26), but are beyond the scope of this article.

The mechanical coupling observed in laminates that are not symmetric in-plane, with respect to an applied stress, or midplane would generally be a problem in most designs, because "warping" is usually undesirable. However, there are special cases where this coupling can be used. For example, an "infinite stiffness" beam can be designed for tension by having an out-of-plane curvature develop to compensate for the in-plane extension. An example of a hygrothermally stable laminate with this behavior would be a (0/90/90/0/90/0/0/90) laminate with the lamina materials selected properly to provide cancellation of the in-plane extension by bending. An application might be in machine tools to provide better dimensional tolerances with less weight. A second example is a tension/torsion member. The optimal pitch distribution along a blade of a tilt rotor aircraft is different for hover and forward flight. The difference in rotor revolutions per minute for hover and forward flight provides a spanwise tensile loading that could provide a torsional deflection in pitch by using, for example, a (+15/+105/+105/+15/-15/-105/-105/-15) hygrothermally stable laminate.

Curved Laminates

Often, large-scale warping or even delamination occurs during the manufacture of curved laminates, such as right-angle stiffeners or leading-edge components even when the laminate is of symmetric stacking sequence. This warping has often been considered a result of poor manufacturing such as resin accumulations or sticking of the laminate to the tooling. However, laminates are frequently made with fibers that have lower coefficients of thermal expansion than the matrix. Hence, the through-thickness thermal expansion coefficient is generally higher than the in-plane coefficient. While flat symmetric and special asymmetric laminates do not warp with temperature change, symmetric (even single-ply) out-of-plane curved laminates warp because of the difference of the inplane and through-thickness thermal expansion.

Hygrothermal stability requires that a curved laminate must be asymmetric through the thickness. Figure 12(a) illustrates a right-angle stiffener after cool-down using a conventional symmetric laminate sequence. The difference in inplane and out-of-plane thermal expansions causes the right angle to become acute. By contrast, a fully asymmetric laminate can be designed such that the right angle is maintained upon cool-down, but the nominally flat laminate away from the right angle warps because it is asymmetric (Fig. 12b). Only when an asymmetric laminate is used in the right-angle region and transitioned to a symmetrical laminate in the laminate arms does a truly shape stable laminate result (Fig. 12c). Resin shrinkage also causes a right angle to become acute during curing. Resin shrinkage can be accommodated by increasing the angle in a mold to greater than 90° for an interior lay-up. The increased angle also helps in part removal. Critical shape stable parts, such as optical benches, require very careful design. Many other factors also can influence the final shape of a complex composite component.

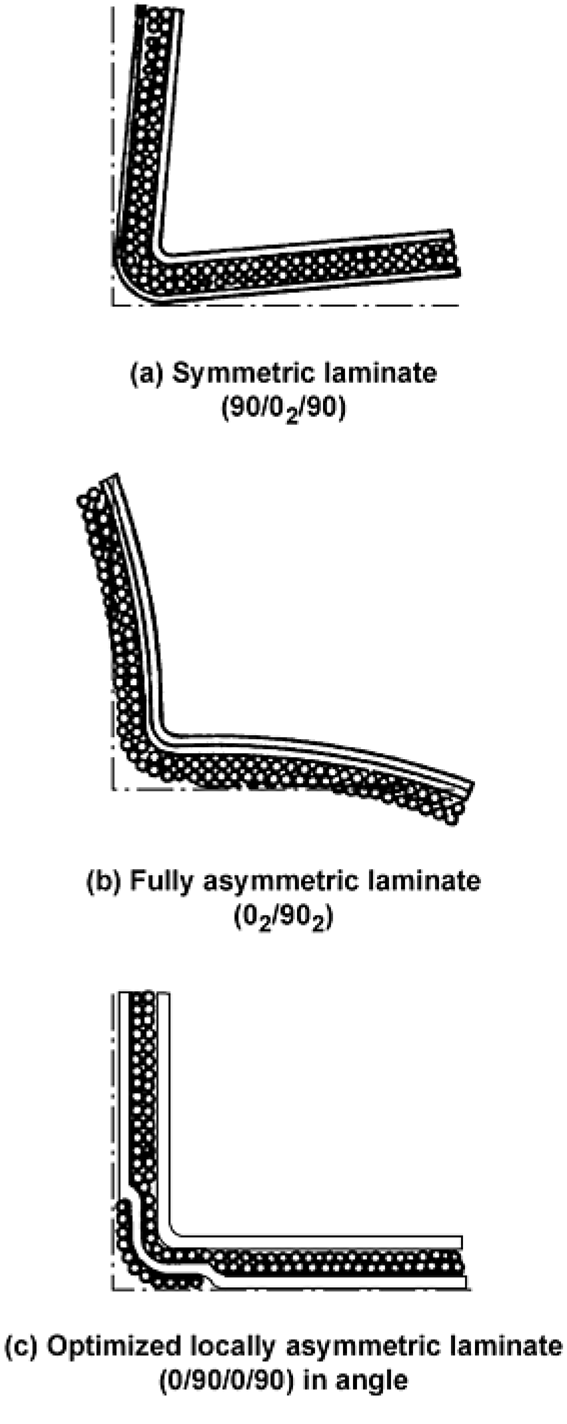

Fig. 12 Shape stability of right-angle laminates after cool-down from cure. All laminates are 90° before cure. (a) Symmetric laminate. The shrinkage in the matrix upon resin curing and the difference in coefficients of thermal expansion in-plane and through-plane cause a right angle to become acute in symmetric laminate. (b) Fully asymmetric laminate. The use of an asymmetric laminate allows the thermal coefficients of expansion to be controlled to compensate for thermal distortions and preserve the right-angle. However, a fully asymmetric laminate would warp in the arms of the right angle. (c) Optimized locally asymmetric laminate. An asymmetric laminate is used in the right-angle region to prevent change of angle with temperature, while the arms are symmetric to eliminate warping. Making the mold at a slightly obtuse angle, which also helps laminate removal from the mold, accommodates the change in angel caused by resin shrinkage. Source: Ref 27

The warping of out-of-plane curved symmetric laminates could be capitalized upon by using them as temperature-sensitive elements. The sensitivity is maximized by having a low axial fiber thermal expansion coefficient and a high

matrix and transverse fiber thermal expansion coefficient. A (0) laminate in a helix with a sharp radius of curvature would be desirable

Controlled Thermal Expansion Composites

The thermal expansion coefficient of higher modulus carbon and organic fibers near room temperature can be slightly negative parallel to the fiber axis, but positive transverse to the axis. Therefore, composites can be made with nearly zero thermal expansion in one direction by the proper combination of fiber/matrix properties, and fiber volume fraction and orientation (Ref 28). The axial modulus of the fiber must be sufficiently high compared to the transverse fiber and matrix modulus, such that the low negative axial expansion of the fiber compensates the higher positive expansion of the matrix and transverse expansion of the fiber. Commonly, a high volume fraction of high-modulus carbon fibers is used to achieve good mechanical properties, and the "excess" negative thermal expansion is eliminated by varying the fiber orientation with respect to the zero-expansion axis. The resulting laminates are good for stiffness-limited applications. However, the poor compression properties, which result from using high-modulus carbon fibers, are a design limitation.

As an example, a space structure for positioning dimensionally critical antennas is exposed to alternating heating/cooling cycles by the sun. This is mainly a stiffness-limited application that needs a zero thermal expansion material. A high-modulus carbon-fiber/resin-matrix composite fabricated into a tubular structure with the fibers oriented in a $\pm\theta$ (or more complicated) set of directions with respect to the tube axis is fabricated to produce a slightly negative coefficient of thermal expansion. The tubular structure is bonded together with positive expansion titanium fittings to form a stiff, lightweight structure with zero overall coefficient of thermal expansion.

As a second example, a semiconductor heat sink should have high thermal conductivity and match the thermal expansion of silicon. Very high thermal conductivity carbon fibers, which also have a negative coefficient of thermal expansion, can be placed into a copper or aluminum matrix to produce a $(0/90)_S$ laminate with a high thermal conductivity and a coefficient of thermal expansion that matches silicon with fiber-volume fractions of about 50%.

Fatigue

Fatigue of composites is often stated as being very good (Ref 29). A uniaxially oriented carbon-fiber composite, loaded parallel to the fibers in tension at low *R* values, usually exceeds a runout of 10^8 cycles at a tensile strength greater than 90%. If the brittle fibers are not broken on the first cycle, they tend to last many cycles. For higher *R* values, the slope of the *S-N* curve is increased. Damage accumulates from broken fibers and cracks in the matrix. Similarly, lower-modulus, but strong carbon-fiber composites are loaded to higher levels of strain for a given *R* value and also have higher *S-N* slopes. An associated decrease in modulus is observed in uniaxially oriented composites during the fatigue testing. In carbon-fiber/epoxy matrix composites, a gradual decrease in modulus occurs that amounts to about 10% before failure. Unfortunately, there may be no forewarning of impending failure, as indicated by a more rapid drop in modulus. Failure can occur in one additional cycle.

Fatigue testing that places high loads on the matrix or interface such as off-axis testing, shear, and/or compression testing generates much worse results. Many laminates show runouts at 10^8 cycles at 50 to 70% of the tensile strength, when loaded in tension. However, substantial microcracking in the matrix can accumulate in off-axis or transverse plies, such that strength in other directions is lowered. Fiber random mat/polymer composites have only 25% of the ultimate tensile strength at 10^8 cycles. Composite fatigue behavior in compression, loaded parallel to the fiber axis or with large matrix shear loading, also is poor. The worst results are noted in transverse tension in a uniaxially oriented specimen, because

large stress concentrations occur on account of the moduli differences and poor interfacial bonding. This same response to fatigue loads is observed in composite bonded joints, limiting their long-term durability.

Composite fatigue resistance can be good or bad depending on the loading conditions and design. If the designer can keep the loads predominantly in the fibers and in tension and the loads in the matrix to a minimum, the composite is likely to have a high fatigue life. If not, the design may be more sensitive to fatigue failure than a corresponding metal part.

Energy Absorption

Composites have been considered for energy absorption applications. Tubular constructions with carefully designed crush-up initiators have the highest energy absorption per pound. The designs are very effective when the load is parallel to the cylindrical axis, but absorb very little energy when the tube is loaded off-axis. Generally, composite structures absorb less energy in a crash than a corresponding aluminum structure (Ref 30).

For example, the impact on the pilot of a helicopter that has lost power and suffers a vertical crash can be much reduced by using a tubular composite energy absorber under the pilot's seat. The helicopter, with its freewheeling rotor, hopefully can be controlled sufficiently to have a vertical impact such that the tubular composite will "crush up" and absorb most of the impact energy. An automobile bumper is not always subjected to impacts from the same direction. The highest-performance energy-absorbing composites are very sensitive to loading direction and may not be a good solution for this application.

Automated Design

The full realization of the potential of composite materials results in structures that may appear quite different than metal structures because of the difference in physical properties. However, the design optimization of a composite involves more variables than metals. While the design of a metal sheet may just consider thickness, a composite requires a minimum of six variables: three thicknesses and three orientations. Additionally, the proximity of yielding to the ultimate strength and the determination of load paths require that detailed analysis be performed early in the design process, often by the finite element method. The complexities of the design process have resulted in the development of computer programs to reduce both cost and time for designing a composite part. While large organizations may have internal capability for composite design, a number of companies have been formed specifically to provide composite design and analysis.

Metal-Matrix Composites

Metal-matrix composites have been developed to improve the specific strength and modulus and more particularly the maximum operating temperature of the lightweight alloys. A goal has been to extend the maximum operating temperature of a low-density metal, by using fiber reinforcement, to replace a denser, higher-operating-temperature metal, for example, an aluminum composite for titanium. Unfortunately, most of the potential fiber/matrix combinations are not thermodynamically stable and react or dissolve, unless coating protection is provided.

Eutectics provide stability, and several systems, such as tantalum-carbide/nickel, appeared attractive for high-temperature turbine applications (Ref 31). The phase diagram determines the volume fraction of reinforcement, and a filamentary microstructure only develops at low volume fractions. However, a low fiber volume fraction of 5 or 10% can substantially reduce creep. Directional solidification (DS) can be used to produce a uniaxially aligned composite. Two problems have limited the application of the DS eutectic composites. Firstly, the mismatch in coefficient of thermal expansion between phases causes thermal fatigue. Secondly, even though a low-energy interface usually exists between the fiber and matrix phases, the microstructure coarsens at high temperature and may even spheroidize, especially under stress. These difficulties have refocused attention upon reactive systems where success depends on development of fiber coatings or having slow kinetic interactions. Unfortunately, metal-matrix composites for replacement of the superalloys have been limited by the unavailability of creep-resistant fibers that are thermomechanically and thermochemically stable with the matrix alloy.

Magnesium, aluminum, and titanium are the most important metal matrices, although copper- and lead-matrix composites have niche applications. A problem with metal matrices is controlling the interaction with the fibers. On the one hand, the matrix may not wet the fiber; on the other, it may dissolve or react to form a compound with the fiber. Aluminum does not wet alumina or graphite, and it is hard to produce void-free composites. By contrast, aluminum reacts with boron and also graphite. Coatings can be used either to promote wetting or to prevent reaction. Silica can be coated on alumina to promote wetting, and silicon carbide can be deposited on boron or carbon fibers to inhibit reaction with aluminum. The matrix composition can also be adjusted to promote wetting by adding a reactive element or by lowering the surface energy. Lithium improves wetting of aluminum alloys on alumina (Ref 32). Similarly, the composition of the matrix can be changed to decrease the chemical potential of a species to decrease the rate of attack on a reinforcement. For example, adding silicon to an aluminum matrix can move the overall composition into a stable aluminum/silicon carbide two-phase field.

For example, the electronics in aircraft often require forced-air cooling to provide adequate lifetimes. A passive, lightweight system that fits into present bays and relies on high thermal conductivity is desirable. The aluminum racks could be replaced with high thermal conductivity carbon fibers in an aluminum/silicon alloy. Inspection for galvanic corrosion would be required, but fiber coatings can minimize degradation.

Large-diameter fibers are more commonly used in metal-matrix composites than in resin- or ceramic-matrix composites. Some of the desired fibers are produced by chemical vapor deposition on a substrate filament that necessitates relatively large diameters ($\sim$100 μm). A large fiber diameter also allows multimicron thick coatings or reaction layers to form without a large penalty in fiber properties. Finally, larger-diameter fibers provide greater thickness of matrix and enhanced plasticity.

The cost of metal-matrix composites compared to unreinforced metal has limited their application. Fiber, coating, and processing costs have led to selective placement of reinforcement, and melt techniques. The casting shrinkage is constrained by the fibers, and porosity can be avoided by squeeze casting (Ref 33). The microstructure of cast metal matrices can be quite different because of the presence of fibers. Nucleation can occur on the fiber surface, and the fiber geometry limits the microstructure that can form. In general, the properties of the matrix are poorer than the optimally processed unreinforced metal. For example, a diesel engine piston made from aluminum would reduce the reciprocating weight. However, the head of the piston is subjected to impulsive loading at a rather high temperature for aluminum. The head would also be less sensitive to thermal fatigue and provide a better cold fit with the cylinder if a lower coefficient of thermal expansion were possible. Finally, a greater wear resistance in the piston head at the cylinder interface would minimize piston slap and allow less expensive piston rings to be used. The selective use of fiber reinforcement just in the head allows the diesel pistons to be squeeze cast at low cost. However, thermal barrier coatings on the head of the piston may be an adequate and lower-cost solution.

Three other processing techniques have been extensively developed for metal-matrix composites. In the first, a layer of carefully spaced monofilament is wound on a metallic foil that is wrapped around a drum. The foil and fibers are slit to form a sheet, and these are stacked up with a cover sheet to make a preform, which is then vacuum hot pressed to produce the composite (Ref 34). The alternate process is plasma spraying the metallic alloy onto the drum to form the foil (Ref 35). In this case, no binding agent is required to hold the fiber to the foil. Either process can make excellent, but expensive, composites; however, care must be exercised during processing to make a fully consolidated specimen without too much interfacial reaction. An alternative low-cost process is the casting of aluminum with silicon carbide particulates for engine blocks and pistons. Strength, maximum service temperature, and wear resistance are increased, while the thermal expansion coefficient is decreased.

The high costs of continuous-fiber composites have driven the development of discontinuous-whisker and even particulate-reinforced composites. The potential performance of these discontinuous composites is much poorer, and the mechanism of strengthening may be only partially by fiber reinforcement with the dispersion strengthening being the major effect. Yet silicon-carbide-reinforced aluminum has a significantly higher modulus and strength, especially at higher temperatures. Although the normal compressive forming processes can shape the composite, the lower ductility and fracture toughness have limited its general application (Ref 36). It is competitive for applications such as snow tire studs, which should be wear and corrosion resistant, as well as low cost.

Properties of Metal-Matrix Composites

Metal-matrix composites offer significantly better mechanical properties than polymer-matrix composites for matrix-dominated properties, such as greater shear, compressive, and transverse tensile strengths. Reinforcement can increase the maximum-use temperature over that of the monolithic material. However, matrix behavior may not be as good as for the unreinforced matrix. For example, the transverse tensile strength of a metal-matrix composite, modeled by a matrix with poorly bonded fibers, is only about one-third of the strength of the unreinforced matrix. Furthermore, the microstructure of the matrix may not be as desirable, and together with the physical constraints placed on the fibers by the matrix, ductility of the matrix is generally much reduced. Metal-matrix composites also can have good electrical and thermal conductivity.

The stress/strain behavior of metal-matrix composites is more complicated than resin-matrix composites because of work hardening and the change in the yield surface with different or multiple loading (Ref 37). (The same considerations make thermal expansion show hysteresis that changes with cycling.) If a residual stress-free metal-matrix composite is loaded parallel to the fiber axis, both the fiber and matrix will be elastically loaded initially (Fig. 13). Upon further loading, the matrix will finally be loaded to its yield stress and then plastically deform, but the fibers will still be loaded elastically. The effective modulus is decreased in this region. Then, substantial fiber failures occur and composites with high fiber volume fraction fail catastrophically. At low fiber volume fractions, fibers break up into critical lengths causing a substantial loss in modulus, and finally matrix failure occurs. These effects have been successfully included in describing the behavior of metal-matrix composites, but design of stable structures that are subjected to temperature cycles is more difficult. The details are beyond the scope of this article.

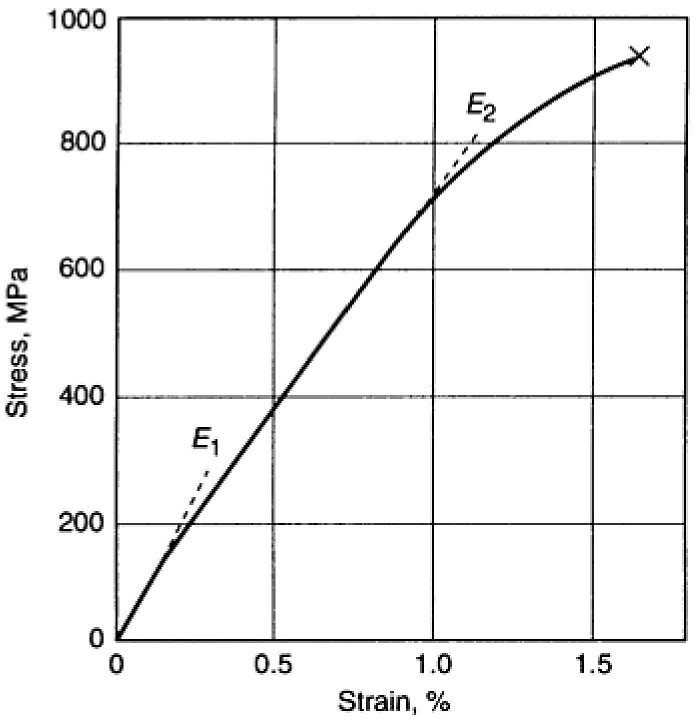

Fig. 13 Stress/strain curve for nicalon silicon carbide fiber in aluminum (1100) matrix. The material has an initial modulus (E_1) of 87 GPa, which is representative of both fiber and matrix elastically deforming. The secondary modulus (E_2) of 70 GPa is indicative of fiber elastic deformation and matrix micro-yielding. For a relatively low-ductility matrix, failure often occurs at the end of the secondary modulus straight line, when the

first fibers begin to fail. For the higher-ductility 1100 aluminum matrix, fiber fractures accumulate during the curved part of the stress/strain plot until final failure occurs. Source: Ref 38

The plastic deformation that can occur in a metal-matrix composite is more apparent for off-axis and transverse loading to the fiber axis (Fig. 14). Loading at 30° produces a stress/strain curve that looks much the same as for the pure matrix except that the strain scale is reduced. The reason is that local matrix deformations around the fibers are much higher than the overall global strains, and failure finally occurs when local strains are similar to the failure strain in the unreinforced matrix. (Triaxial tensile strains are also present in the matrix, which also tends to reduce ductility.)

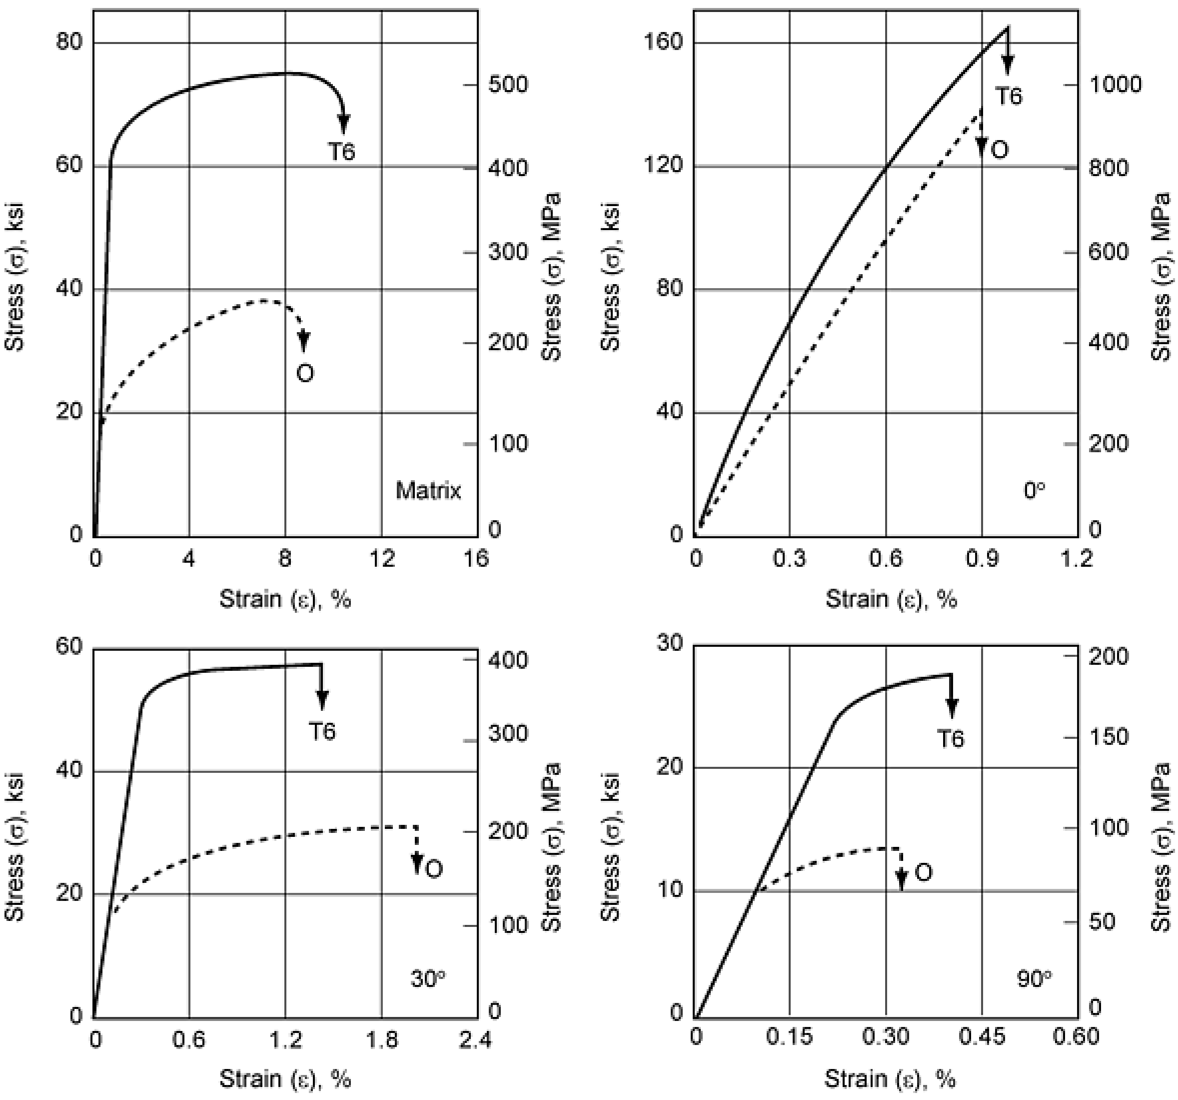

Fig. 14 Effect of loading direction on uniaxial boron fiber/aluminum (7075). Results are for fibers oriented at 0, 30, and 90° with respect to the load and pure matrix in the T6 and O conditions. Source: Ref 39

Fatigue properties in the axial direction of the fibers is excellent, but fatigue for off-axis loading, which relies on the fatigue behavior of the matrix, can be worse than for the unreinforced matrix. The accumulation of failed fibers and matrix cracks in fatigue testing results in loss of modulus. This may continue until composite failure occurs. However, in some laminate constructions or composites with low fiber volume fraction, damage may develop to a stable condition (shakedown), whereupon further fiber or matrix damage occurs slowly. The drop in modulus may be as great as a factor of two during shakedown, which may require part removal because of reduced stiffness.

Ceramic-Matrix Composites

The demand for composites that can operate at higher temperature has driven the development of ceramic-matrix composites. Tremendous barriers stand in the path for successful application of these composites in which the properties of the fiber and matrix may be very similar, and indeed the chemical composition of both may be identical. The lack of cost-effective and creep-resistant fibers, stable crack-stopping interfacial coatings, and high strain-to-failure matrices all lead to poor-extended-life, oxidation-prone, high-temperature composites. Yet, the successful application of car-bon-fiber/carbon-matrix and silicon-carbide/silicon-carbide composites to rocket nozzles and reentry vehicles illustrates the potential of these materials if environmental stability can be achieved. While ceramic composites might be used at lower temperatures because of their corrosion resistance, they are mainly considered for high and extreme temperatures often as the last resort.

The mechanical behavior of these composites, which have similar constituent moduli, is quite different from resin-matrix composites, especially because the strain to failure of the matrix is typically smaller than that for the fiber. The fibers are added not only to provide high-temperature creep resistance, but more importantly to provide damage tolerance and a more graceful failure at room temperature. When a ceramic-matrix composite with uniaxially oriented fibers is loaded in tension parallel to the fibers, the load is relatively evenly distributed between the fiber and matrix, the exact ratio being determined by the relative moduli and volume fractions. For relatively strong coupling between the fiber and the matrix, the composite fractures when the first crack occurs in the *matrix* (Fig. 15a). Often, there may already be surface cracks from specimen preparation. The composite strength may be lower than a monolithic specimen of pure matrix material, as it frequently is not possible to process the matrix to as high a quality with fibers present. The strength and toughness of commercially available composite products will generally be higher than for monolithic materials. Better processing eliminates many of the defects by filling in voids with more and better matrix material. Matrices with higher fracture toughness would help increase the strain at which first cracking occurs, as would lower modulus. However, the fracture toughness decreases as the refractoriness (bond strength) of the material increases. Low matrix fracture toughness is the likely result for the highest temperature applications. However, combining several techniques to improve fracture toughness, such as adding whiskers to the matrix and placing multiple crack-stopping interfaces within the matrix can increase the strain for first matrix failure.

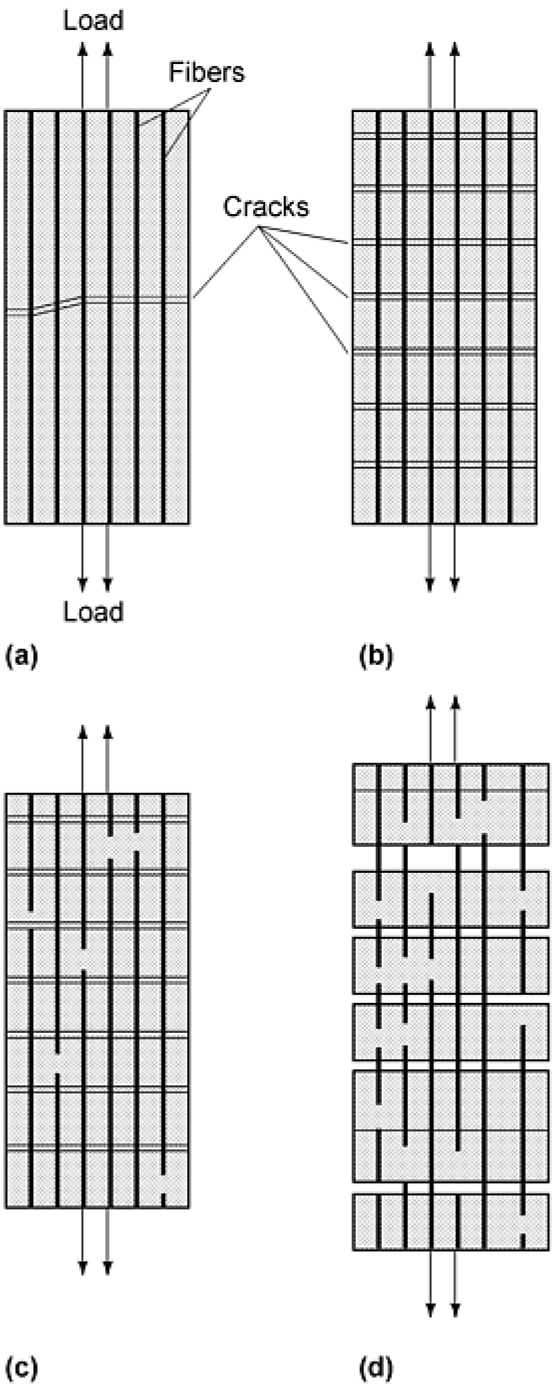

Fig. 15 Illustration of ceramic-matrix composite failure process. (a) The crack, which initiates in the matrix, propagates through both matrix and fibers in the composite when strong interfacial bonding exists. (b) For intermediate or low interfacial bonding, the matrix crack runs through the matrix but around the fibers. Multiple cracks accumulate if the fibers bridging the cracks can sustain the load. (c) After attaining multiple matrix cracks with an equilibrium spacing, fibers fail at flaws with increasing load, and not necessarily in the bridged regions of highest stress. (d) Fibers pull out of their matrix sockets with further extension.

Decreasing the coupling between the fiber and matrix sufficiently allows the first crack in the matrix to deflect around the fibers such that the fibers will bridge the cracked matrix and sustain the load if the fiber strength and volume fraction are high enough (Fig. 15b). As the load is increased, more matrix cracks form and finally yield a specimen with a relatively uniformly spaced set of cracks in the matrix, all bridged by the fibers. The spacing of the cracks is determined by the fiber/matrix coupling: the poorer the coupling, the wider the spacing. Finally, there is insufficient length between cracks to transfer the load, which only the fibers are carrying in the bridging regions, to the matrix to cause further cracking. A large drop (~50%) in modulus can occur with poor interfacial bonding when the matrix cracks. The design may be

limited by this decrease in modulus or by resonant frequency changes. Further loading causes failure of fibers, and finally at one bridging section the remaining fibers can no longer support the load and the specimen fails. The probability for failure of the fibers is highest in the bridges, because the matrix carries no load. However, there is a distribution of strength-reducing flaws along the length of the fibers, and there will be fracture of fibers away from the bridged matrix crack, albeit with a decreasing frequency with distance from the crack (as the matrix picks up load) (Fig. 15c). The last step of the process is the pullout of the fractured fibers from their sockets in the matrix (Fig. 15d). Much energy can be absorbed, as the apparent strain can be quite high. Studies have shown that this pseudometallic, stress-strain behavior can be achieved in ceramic composites.

Constituent Selection

Ceramic-matrix composites are likely to be used at high temperature and are usually fabricated at high temperature. In addition to the usual considerations of physical properties such as specific modulus and strength, creep and stress rupture become the limiting mechanical properties for high-temperature applications (Ref 40). The most creep-resistant ceramic is graphite, followed by silicon carbide, titanium diboride, and silicon nitride. Yttrium-aluminum-garnet (YAG), mullite, and sapphire appear to be the most attractive oxides (Ref 41). Both fibers *and* matrices must be creep resistant. For lower-temperature applications, glass-matrix or glass/ceramic-matrix provide a combination of thermal expansion coefficient, fracture toughness, and low modulus that allow very good composites to be produced. The selection of fiber and matrix material combinations is very much limited by thermochemical and thermomechanical incompatibilities. For example, carbon fibers in any oxide matrix are thermodynamically unstable above 1500 °C. Similarly, a mismatch of thermal expansion coefficients much above 2 μm/m · °C causes microcracking of the composite.

The problem of selection of a ceramic composite system is compounded because a weak interface is necessary to control the fracture. A third interfacial phase between the fiber and matrix is often added, especially when the matrix and fiber have the same chemical composition, such as with a silicon-carbide-fiber/silicon-carbide-matrix composite. The interfacial materials generally have a layer structure, although highly porous interfacial phases have also been used. However, no environmentally stable layers have been found for the higher-temperature composites (>1200 °C). Model systems usually have used graphite. Boron nitride, which has some oxidation resistance to 1100 °C, has been found to be an effective crack-stopping interfacial material also. Oxide-layer compounds, such as synthetic micas, are useful for temperatures as high as 1100 °C. However, the interface between fiber and matrix remains a problem, and present interfacial coatings add substantially to the composite cost.

Ceramic-matrix composites are not as well developed as polymer-matrix composites, with the exception of carbon-fiber/carbon-matrix composites. Carbon/carbon composites are used extensively for aircraft brakes, shuttle tiles, rocket motor nozzles, and reentry vehicles. For other ceramic-matrix composites, the designer must select one of the few systems that are available. Much stronger interaction with the materials supplier is required, because the processing and properties are very much producer dependent.

Properties of Ceramic-Matrix Composites

The elastic properties can be calculated using the equations described in the sections "Calculation of Lamina Properties" and "Symmetric In-Plane and Through-Thickness Laminates" in this article. The major difference with ceramic-matrix composites is that the moduli of the fiber and matrix are frequently similar, so that the elastic properties are more isotropic.

The fracture behavior of ceramic-matrix composites differs from that of polymer- or metal-matrix composites in that the failure strain of the matrix is less than that for the reinforcement. The stress/strain curve for a uniaxially aligned fiber specimen, loaded parallel to the fibers is shown in Fig. 16 (Ref 42). Both matrix and fibers are being loaded initially, until the failure strain of the matrix is reached, and the matrix starts fracturing. There are three different limiting behaviors depending on the interfacial bonding: (1) high interfacial bonding causes catastrophic failure, (2) intermediate bonding causes a change in slope, (3) poor bonding causes a load drop with a subsequent slope proportional to just the modulus and volume fraction of the fibers. For low or intermediate interfacial bonding and a volume fraction and fiber strength sufficiently high to support the applied load after matrix fracture, composite fracture does not occur, and multiple matrix cracks will accumulate. In the limit, as bond strength goes to zero, the ceramic matrix behaves as if it has holes. These "holes" act as stress raisers. The final crack spacing is determined by the strength of the matrix and inversely on the maximum shear stress that can be sustained at the fiber/matrix interface. The relationships for multiple matrix cracking, and the final matrix crack spacing are (Ref 43):

$$\sigma_{CMu} < \sigma_{Fu} V_F \quad \textbf{(Eq 12)}$$

$$L = V_M \sigma_{Mu} R / V_F \tau \quad \textbf{(Eq 13)}$$

where σ_{CMu} is the composite stress when first matrix cracking occurs; σ_{Mu} and σ_{Fu} are the matrix and fiber ultimate strengths, respectively; R is the radius of the fiber; τ is the shear stress at the fiber/matrix interface; and L is the spacing between matrix cracks.

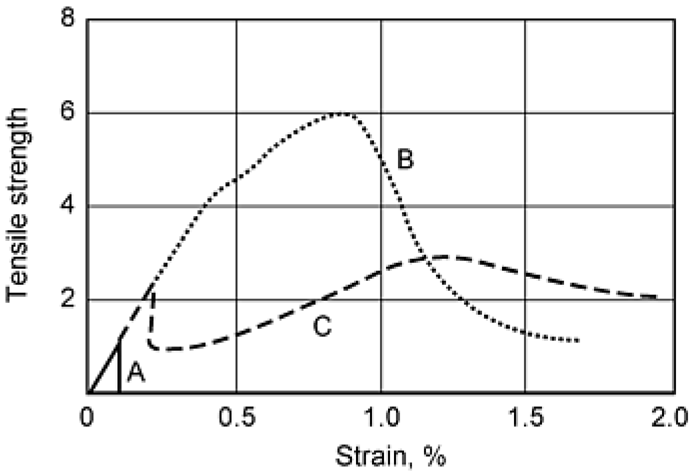

Fig. 16 Stress/strain curve for a typical uniaxial ceramic-matrix composite loaded parallel to the fibers. The solid line (A) shows the behavior for strong interfacial bonding and catastrophic failure with the first matrix crack. The dotted line (B) indicates intermediate bonding behavior such that the fibers bridge the matrix cracks, but with short fiber/matrix debonding near the cracks. The dashed line (C) illustrates the stress/strain curve for very weakly coupled fiber and matrix. In the limit, the matrix contribution to the modulus is completely lost after matrix fracture.

In ceramic-matrix composite systems that retain high frictional or chemical bonding interaction between the fiber and the matrix after matrix fracture, a simple change in slope occurs in the stress/strain curve as the matrix begins fracturing (Fig. 16). In other systems, there is loss of the matrix stiffness if coupling between fiber and matrix is lost when matrix fracture occurs. The stress/strain curve under displacement control may show a load drop much like yielding, or become horizontal, until the load increases again with strain, but this time only with the modulus contribution from the fibers. (The actual curve may differ because of residual stresses between the fiber and matrix.)

The microcracking of the matrix not only results in loss of modulus, but also allows internal oxidation to occur. Parts could be designed to stress or strain levels below which matrix cracking occurs. While it might be expected that the matrix would crack at similar strains as for the unreinforced ceramic matrix (0.05 to 0.10%), the strain for matrix cracking was shown to be enhanced (Ref 43):

$$\varepsilon_{Mu} = [24\tau_O \gamma_M E_F^2 / E_C E_M^2 D_F (1 - V_F)]^{1/3} + E_F V_F \Delta\alpha \Delta T / E_C \quad \textbf{(Eq 14)}$$

where ε_{Mu} is the reinforced matrix strain at failure, τ_O is the interfacial shear strength, γ_M is the matrix fracture energy, D_F is the fiber diameter, $\Delta\alpha$ is the difference in thermal expansion coefficient between fiber and matrix, and ΔT is the difference between the stress-free temperature and the use temperature. The stress-free temperature is often assumed to be the processing temperature.

Although the fractional exponent on the first term minimizes the effect of the parameters, the wide range that some of the parameters can have produces significant changes in the strain. High matrix fracture energy, high fiber modulus and volume fraction, small fiber diameter, and low matrix modulus all increase the matrix failure strain. Increasing the interfacial shear strength also raises the matrix failure strain, but the value must not exceed that which causes brittle

failure. One approach, which has doubled the matrix microcracking strain, is reinforcing the matrix with about 15% of fine whiskers.

The second term in the equation is the residual stress that arises from the mismatch in the coefficients of thermal expansion between the fiber and matrix. An axial compressive residual stress would be present in the matrix at room temperature if the fiber thermal expansion coefficient is larger than that for the matrix, because the composite is generally processed at high temperature. Unfortunately, the thermal expansion coefficient of the fiber is likely to be smaller than the matrix, placing the matrix in residual axial tension.

The average matrix strain-to-failure in a composite can frequently be increased to values of 0.4% or more, which combined with the 1% or better strain to failure of the fiber, can produce a stress/strain curve mimicking a ductile metal, albeit with very limited strain capability. A problem is that the first few matrix failures are observed at strains only slightly higher than the unreinforced matrix. Therefore, a prudent assumption is to assume that matrix microcracks will always be present that may allow internal oxidation and embrittlement.

The ultimate tensile strength of uniaxially aligned composite, loaded parallel to the fibers, is given by the bundle strength and volume fraction of the fibers bridging the matrix cracks:

$$\sigma_{Cu} \sim \sigma_{Fu} V_F \qquad \textbf{(Eq 15)}$$

where σ_{Cu} and σ_{Fu} are the ultimate tensile strengths of the composite and fiber bundles, respectively.

The bundle strength of the fibers cannot be measured on a gage length that approximates the short gage length in the cracked matrix region of the composite, but might be approximated from resin- bonded strand tests. Because fiber volume fractions often are about 50% in a uniaxially aligned ceramic composite, the axial ultimate tensile strength will be about one-half of the fiber bundle strength, if the interfacial coupling has been properly adjusted to prevent brittle fracture. If a fabric is used, somewhat less than 25% of the tensile strength of a bundle can be obtained because of the over/under construction in a fabric and the effective fiber volume fraction in the load direction.

The toughness of a ceramic-matrix composite can be caused by at least five different mechanisms, which can act independently or in a combined manner. However, the work to fracture, the area under the stress/strain curve, is generally dominated by the "pull out" of broken fibers from their matrix sockets. Although it is generally desirable to have little scatter (high Weibull modulus) in the strengths of fibers in order to attain the highest composite, ultimate tensile strength, no pullout occurs when there is no variation in fiber strength. All fibers would fail simultaneously in the highest-loaded regions at the matrix cracks. Pullout requires that fibers fail at flaws away from the matrix cracks, and then the broken fibers drawn out from the matrix sockets. The work of pullout (W_P) for a multiple matrix cracked composite (in ft · lbf) is (Ref 44):

$$W_P = 0.083\,[(m - 1)\,(m + 2)/m^2(m + 1)^{2/(m + 1)}]\; V_F(0.5D_F)^{3m/(m + 1)}\,[\sigma_O^{2m/(m+1)} / \tau^{(m - 1)/(m + 1)}] \qquad \textbf{(Eq 16)}$$

where m is the Weibull modulus, σ_O is the Weibull strength scale parameter, D_F is the fiber diameter, and τ is the interfacial shear strength.

For m = 8, typical for commercially produced fibers, the equation reduces to:

$$W_P = 0.008\, V_F\, D_F^{2.7}\,[\sigma_O^{1.8}/\tau^{0.8}] \qquad \textbf{(Eq 17)}$$

The optimal Weibull modulus for maximizing work of fracture is about 4. (There will probably not be any development of fibers optimized for maximum work of pullout in the near future due to the limited market.) A high volume fraction of large-diameter fibers with high strength, but with a low interfacial strength produces a maximum work of pullout. A comparison with the matrix microcrack strain equation shows that high fiber volume fraction and strength are beneficial to both. However, the effects for fiber diameter and interfacial shear strength are opposite. A ceramic composite cannot be optimized for both the work of pullout and the matrix microcrack strain simultaneously.

The strength of a uniaxial ceramic-matrix composite that is loaded off-axis is low. This result is a consequence of the poor interfacial shear strength between the fiber and matrix that is required to control fracture. Multiple-ply laminates with off-axis oriented plies must be used to sustain off-axis loads.

The materials selected depend very much on the application. For inert atmosphere or very short time applications (tens of minutes), unprotected carbon fibers in a carbon matrix provide the best mechanical properties, especially at very high temperature. Creep is low until 2200 °C. Coated carbon/carbon composites with internal additives can have lifetimes in oxidizing environments up to 1700 °C for as long as 100 h, but not very reproducibly. Silicon carbide or nitride provide much better oxidation resistance, but would probably be creep limited at temperatures above 1500 °C for the carbide and somewhat lower for the nitride, even anticipating future improvements. At present, oxide systems appear limited to 1200 °C and up to 1300 °C in the future. The exact values all depend on stresses, time, and temperature, and the development of suitable interfacial materials.

Large Composite Structures: Joints, Connections, Cutting, and Repair

A major advantage of composites is that large integrated structures can often be designed with a major reduction in parts count and assembly time. The number of mechanical fasteners is often a small fraction of the number used in metal structures. While it is sometimes possible to design a large composite in which loads are predominantly carried by the fibers, usually there will be regions that rely only on the matrix for load transfer from one major volume to another. Several parts may be cocured together so that the matrix resin acts as the adhesive. This area behaves much as a bonded joint. Mechanical fasteners have been added to increase the reliability, but surprisingly performance has sometimes been decreased because of the stress concentrations and delamination damage at the free edge of holes. Extensive use of mechanical fasteners is costly with carbon-fiber/resin composites, because the fasteners are generally made of titanium to minimize galvanic corrosion; use of coated fasteners would avoid corrosion and lower cost.

Stitching has also been applied successfully using a tough fiber such as an aramid as the stitching yarn, as a method of improving interlaminar properties and minimizing edge delamination. Stitching pierces the laminate with a minimum of laminate fiber damage and displacement. Optimization of stitch spacing and yarn denier and tension has been performed for a number of different laminates and structures.

While composite materials are especially amenable for making large integrated structures, it should always be realized that damage is likely to occur during the lifetime of the structure. The structure must be designed for easy and efficient repair. Consideration of where cuts should be for removal of damaged material, and flanges for attachment or bonding of repaired sections, and so forth, is required.

Composite materials also offer the possibility for in situ structural-integrity monitoring by incorporating sensing fibers within the composite. A number of studies have shown that optical and strain-sensitive fibers can be used to measure loads and structural integrity. However, these techniques have yet to achieve wide application.

Variance and Scaling Considerations

Composites traditionally have used brittle fibers, because of their otherwise superior properties. For simplicity, consider a composite with the fibers all aligned parallel to the load direction. While the most probable state of the composite would be to have the worst flaws in each fiber randomly distributed along the fiber length, there is a small chance that all the worst flaws are located at the same distance along each fiber. (If there are periodic processing-induced defects, the odds become worse that the flaws correlate.) The question is how does the variability, as measured by the Weibull parameter, of composites compare to that of engineering metals? For well-developed composite systems, made in simple, flat laminates, the Weibull parameter for small specimens can be as high (20 to 24) as for aluminum sheet in the rolling direction, and even better than aluminum in the transverse direction. However, strengths of longer laminates have often been lower than predicted by simple Weibull scaling (Ref 45). There are two problems. Firstly, a large composite laminate may not be made in the same way as the smaller test laminates and more and worse flaws are introduced. Secondly, the small test specimens do not sample the worst flaws very well, which actually cause failure of the long laminate. By contrast, Weibull scaling of strength, when the width is increased, underpredicts the strength of the composite. (The strength does not drop off as fast as predicted.) The designer must be aware of the effect of scale on strength. Additional discussion of Weibull statistics is provided in the article "Design with Brittle Materials" in this Volume.

Load, Heat, and Electrical Current Transfer

The large difference in properties that often exist between fiber and matrix make transfer of load, heat, and electricity to a composite part very inefficient. The problem is easily illustrated in resin-matrix composites, because of the low modulus, and low thermal and electrical conductivity of most polymers. Most of the load, heat, or electrical current is usually transferred to a composite through the resin to the fibers from the sides and not directly to the fibers from the end (Fig. 17). In the case of mechanical loads, the load is transferred through shear stresses at the surface, and a tensile stress builds up in the composite from the end. A gradient in tensile stress also is present through the thickness, but disappears with sufficient length as the load is diffused throughout the composite. The distance along the composite that is required to reach approximately a constant stress is much longer in a composite than in a metal. While the stress can be considered constant in an isotropic metal within approximately two thicknesses for a sheet, the value for composites can vary from 6 to 40, the exact value depending on the composite architecture and materials. Hence, a designer must be more careful in transferring load to a composite to prevent overloading outer fibers. Load-transfer distances are much greater than in metals, and joints are less efficient.

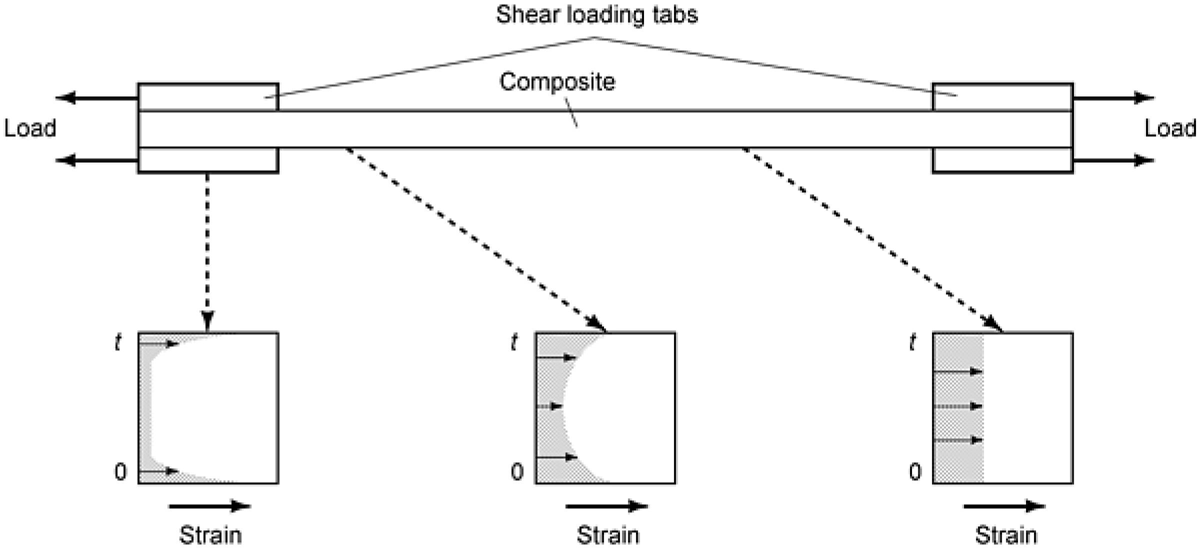

Fig. 17 Transfer of load into a uniaxial composite. The transfer of load through shear produces high stresses in the outer ply fibers at the grips. The distance along the composite that it takes for the load to diffuse

throughout the cross section is much greater than in a metal. The stress profiles through the thickness are illustrated at several positions along the length of the composites

Fiber-reinforced composites have also been considered for heat-transfer applications, because of the development of very high thermal conductivity carbon fibers (five times the thermal conductivity of copper at room temperature). The thermal conductivity is at its maximum value somewhat below room temperature and decreases to low values near 0 K. Above the maxima, the thermal conductivity decreases approximately inversely with temperature. Hence, the very high thermal conductivity can only be achieved in near-room-temperature applications. These high thermal conductivity carbon fibers have been used in resin, metal (particularly aluminum), and carbon matrices. Flash laser thermal diffusivity experiments have shown that high thermal conductivity can be achieved in resin-matrix composites, when the laser beam directly impinges on the fiber ends in a uniaxial composite. However, the effective thermal conductivity in many real designs is much lower, because the heat must be transferred through the resin matrix, and the heat flow never becomes uniform through the cross section of the part. In the corresponding case for electrical conduction, uniform current flow is even more difficult to achieve. Adding an electrically or thermally conducting powder to the matrix resin can help alleviate the problem.

Metal-matrix composites allow better transfer of heat to the high thermal conductivity fibers, provided good fiber/matrix interfacial thermal contact can be maintained. Although aluminum can galvanically corrode with carbon fibers, the low density and high thermal conductivity makes this combination attractive especially for space and aeronautical applications. Protective coatings are available for carbon fibers to minimize corrosion.

Joint Design

Only one-half of the potential weight savings is often achieved when using composites because of the necessity of joints. The inherently inefficient load transfer into most composites, especially polymer-matrix composites, means that joint design is often a driving factor in composite design. Frequently, sections are thick and load paths complicated, which requires careful, and three-dimensional, analysis. Design of a joint is often more difficult than that of the rest of the composite part. A primary decision is whether to use bonded or mechanically fastened joints. Studies have shown that bonded joints can be more efficient than mechanically fastened joints. However, the questionable reliability and longevity of these bonded joints, especially if off-axis peeling stresses are present, have often resulted in the use of mechanical fasteners. Mechanical fasteners must be used if easy disassembly or access is required.

Mechanically Fastened Joints. The behavior of mechanically fastened joints is similar to but more complicated than the behavior of similar joints in metal. Not only is the strength dependent on geometry as with a metal, but also on the fiber orientations. Numerous composite joint configurations have been tested and evaluated. Only the major conclusions are presented. The important factors affecting joint strength are joint type, fastener, geometry, and failure mode.

Several types of mechanical joints have been used with composite materials. The choice of joint type depends on the application. Single- or double-lap designs with rivet (pinning) or bolting are frequently used. Riveted joints often provide adequate strength in carbon- or glass-fiber- reinforced resin-matrix composites, but bolts offer the greatest strength. Higher-bearing-strength bolted joints result if the clamping pressure is increased to an optimum by using a higher bolt tightening torque. Additionally, washers, and a carefully reamed hole that closely fits the bolt, produce higher-strength joints.

Mechanically fastened joints in composites display the same failure modes as observed in metals: net-section tension, edge-section shear, end-section bearing, and combined modes (Fig. 18). Geometrical factors as well as fiber orientations determine the failure mode. The geometrical factors of width (pitch), end distance, and diameter influence the behavior of composite joints, just as they do in metals (Ref 47, 48) (Fig. 19). End distance is defined as the distance from the end of the joint to the center of the closest hole, and width is the distance from the sides of the joint to the center of the nearest hole. End distance and width must be above a certain minimum if full bearing strength is to be obtained. Below these minima, tensile failure occurs if the width is too small, and shear-out or cleavage if the end distance is too small (Fig. 18). While all materials follow the same trend, the full strength occurs at differing w/d and e/d ratios for different materials and stacking sequences. However, values of w/d and e/d of 5 appear adequate to achieve a bearing failure in most resin-matrix composites. Adding fabric plies for reinforcement around holes is a very efficient way to reduce w/d and e/d values to below 5, although the thickness of the composite will be increased in the local region.The hole diameter compared to the laminate thickness, d/t, has a negligible effect if the hole is optimally clamped, but should be below 1 if not.

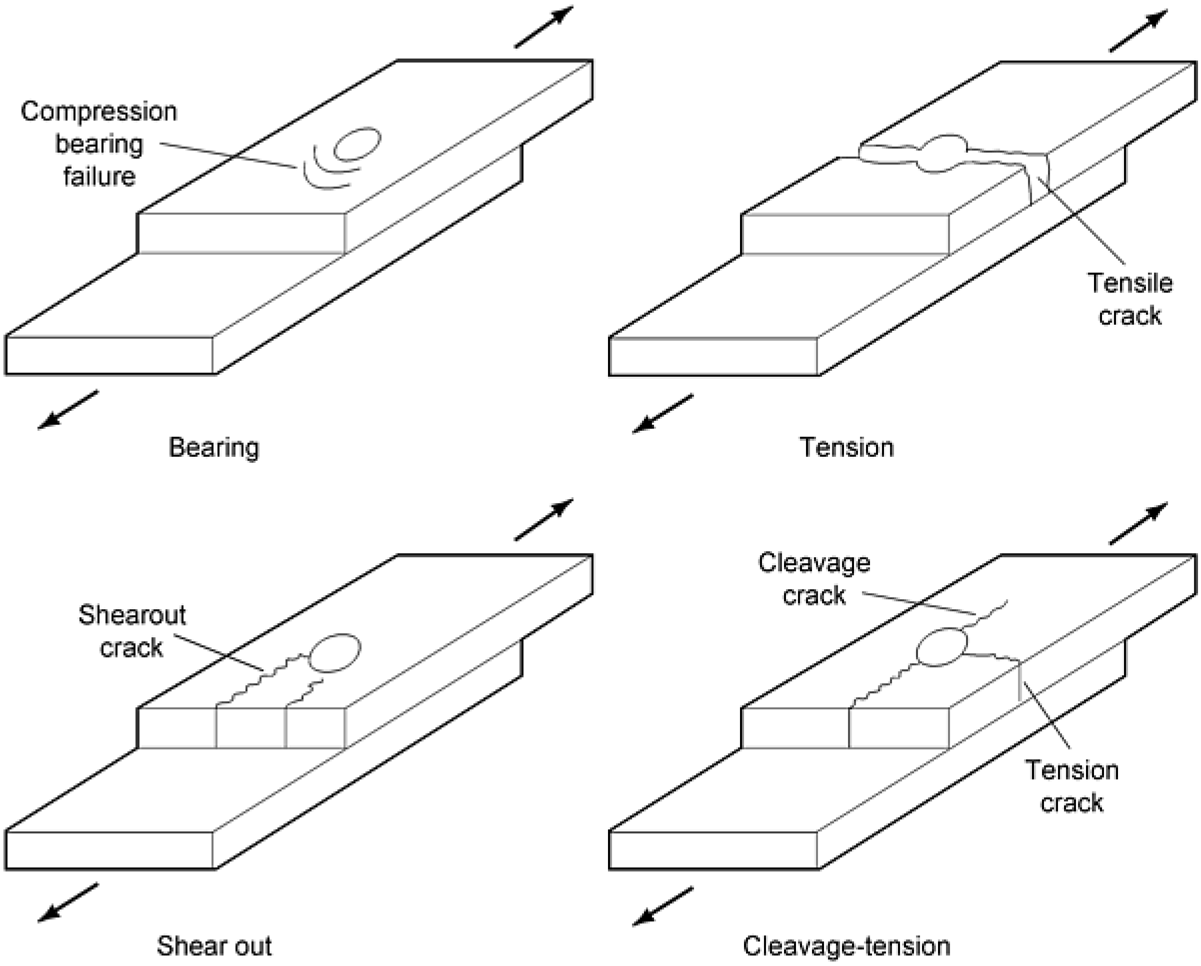

Fig. 18 Failure modes in bolted joints. Failure not only depends on the geometrical dimensions, but also on the laminate construction. Arrows show direction of tensile loading. Source: Ref 46

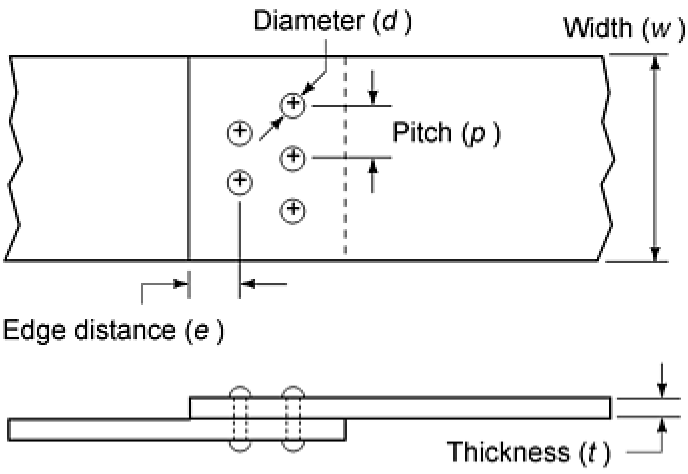

Fig. 19 Definition of bolted-joint geometry terms. Source: Ref 46

Bonded Joints. A bonded joint consists of three components with different mechanical properties: the adhesive or joining material, and the two parts that may be the same or different material. A large number of variables influence the

load-carrying capabilities of an adhesive joint. Manufacturing variables include composition, preparation of the adhesive and adherends, and the joint geometry. Joints may also involve use of brazing with or without chemical reaction in metal or ceramic composites. The behavior of a bonded composite joint, as with mechanically fastened joints, is more complicated than its metal counterpart. The anisotropic nature of the material is significant, as are the low values of interlaminar and through-thickness modulus and strength for resin-matrix composites.

Various types of adhesively bonded joints are used in composites (Ref 49) (Fig. 20). The selection of joint shape is influenced by the type of assembly (thick/thin, etc.), bending moments, tooling requirements, and costs. While the scarf and beveled lap joint provide more uniform stress distributions and high strength, they present several fabrication problems, especially in thin sections. They are expensive to machine, the feather edges tear easily, the bonding jigs are expensive, and the pressure must be applied with care.

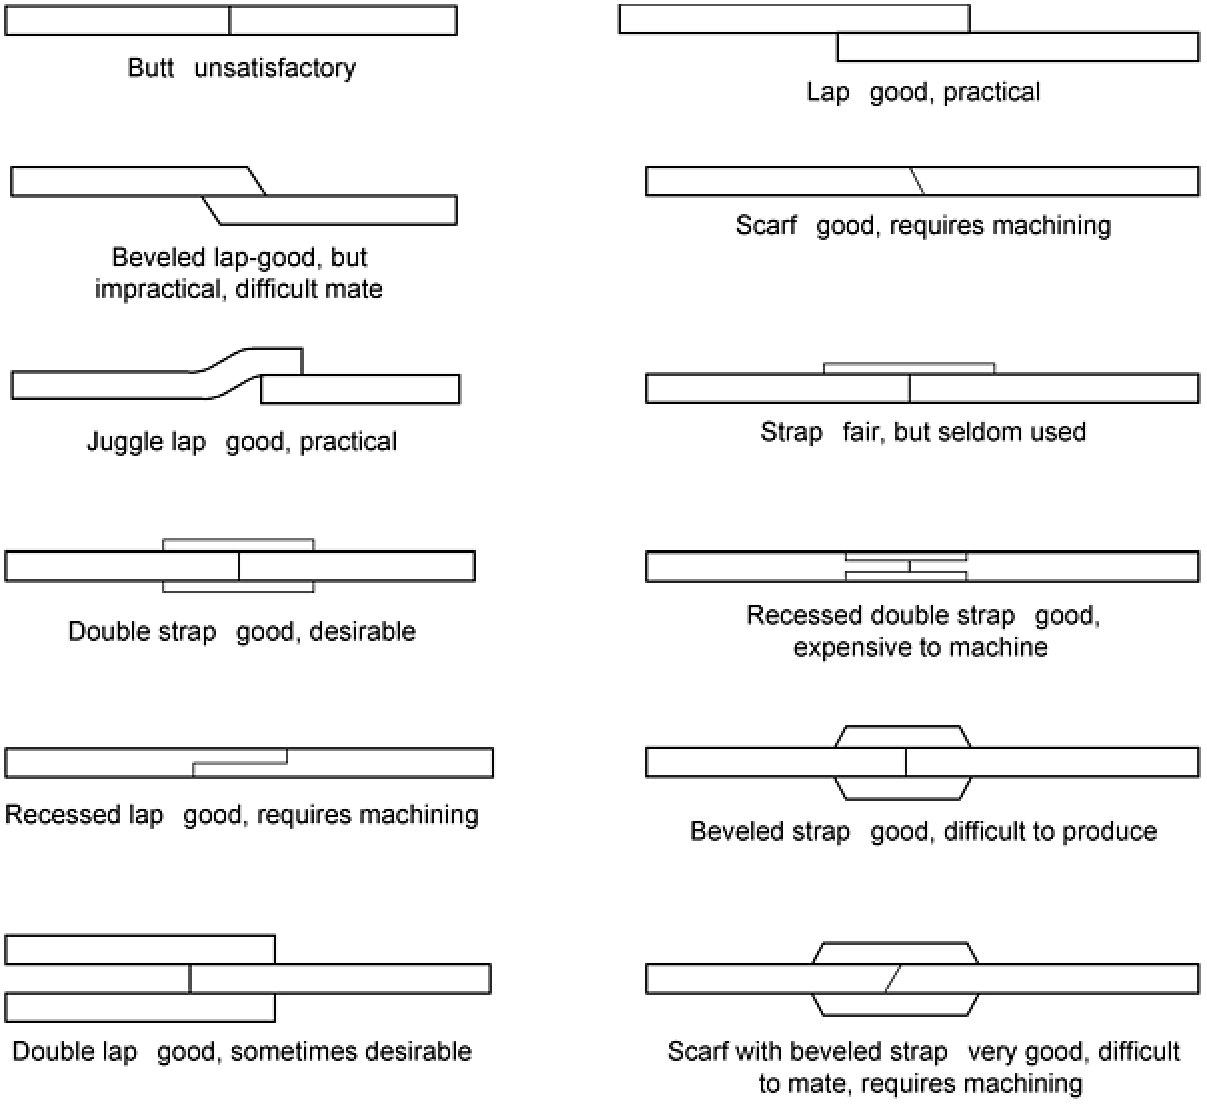

Fig. 20 Types of bonded joints. Many variations are possible, but difficult machining and assembly often eliminate more complex designs. The best bonded joints are those with the largest bond areas and minimum peeling stresses. Source: Ref 46

Compared to failure in metal joints, a larger number of failure modes can be identified in composites, due to their anisotropic nature. Failure can be tensile, interlaminar, or transverse in the adherends (Fig. 21). In the latter two cases, failure may either be in the resin or at the fiber/resin interface in a resin-matrix composite. A cohesive failure mode can also occur in the adhesive.

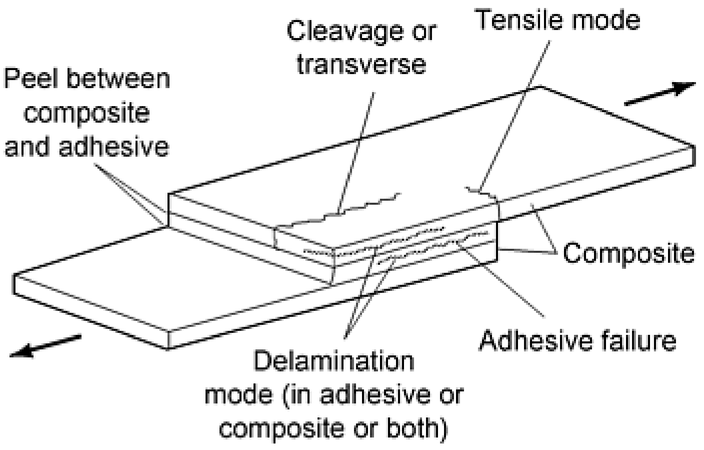

Fig. 21 Failure modes in bonded joints. Arrows show direction of tensile loading. Source: Ref 46

Most of the adhesives used for structural purposes are relatively strong in shear and weak in cleavage or peel. Therefore, the designer should attempt to place the adhesive in shear and minimize peel and cleavage stresses. The stress distribution depends on the joint geometry and the mechanical properties of the adhesive and the adherends. The strength of a simple, straight lap joint is directly proportional to the width of the bond, but increases to an asymptotic value with overlap length. The length required to reach the asymptotic strength depends on the particular material system, but values in excess of 40 are typical. Joint strengths are improved if identical adherends are used (if not, the in-plane and bending stiffness should be equalized), adherend stiffness is increased and adhesive moduli decreased, and as large an overlap as possible is used.

As a general rule, bonded joints are more suitable for lightly loaded joints where their high efficiency can be fully realized. Mechanically fastened joints are invariably used in high risk, highly loaded joints that are subjected to severe fatigue and environmental conditions. The major penalties involved in the use of mechanical joints are the increased weight, part count, and associated cost. However, there are many notable exceptions to this generality in which careful design has allowed the use of bonded structures in complex but critical parts. A combination of fasteners and bonding is the most structurally efficient and reliable arrangement in many cases.

Cut Edges

Resin-matrix composites are often sawed and then routed to final dimension, or cut by water jet. While the cut surface may appear smooth, interlaminar cracks may be introduced because of the poor interlaminar strength of resin-matrix composites. Even if no cracks are present, the free edge can act as an initiation site for cracking as high interlaminar stresses are often present at the free edge. Good design should minimize the number of free edges in the design if possible. Because free edges are often sites for failure in fatigue applications, a thin coating of a tough resin, even on the very smooth edges, has been found to increase fatigue life by a factor of ten.

A damaged surface often results when an abrasive wheel is used to cut metal or ceramic-matrix composites. The surface cracks may act as failure sites, especially in fatigue applications. A more important problem is that the cut edges expose reactive fibers and interfacial coatings to the environment.

Surface Coatings

Paints and wear-resistant coatings often have to be stripped and recoated. The similarity of paints to resins in resin-matrix composites often makes stripping difficult and usually more expensive than the application cost. However, the total life-cycle cost is often not minimized, because different groups manufacture and refurbish the composite structures. A goal of "paint for life" may be attractive for many applications.

Design for Manufacturing

Processing and fabrication costs could be reduced if structures were designed for manufacturing as well as performance. Composite materials are generally designed to maximize performance, and much touch labor is often used to manufacture these designs. Many composite laminates are fabricated by laying the laminate plies against a tooling surface, vacuum bagging, and then autoclave curing. While the surface molded against the tool can be good, the laminate surface nearest to the vacuum bag is often quite rough and the thickness is not well controlled because of variances from ply thickness and processing. The local roughness, often produced from "peel ply," can act as a beneficial spacer in bonding, but the variable thickness often requires shimming to maintain tolerances. Use of large closed metal molds can eliminate this problem, but they are too expensive to use for limited production runs. The use of high throughput, but limited geometry technology, such as pultrusion, filament winding, and braiding should be considered to reduce touch labor. Novel technology such as fast winding of a simple shape, with subsequent deformation to a more complex shape, should be considered for adding more versatility to these otherwise more limited processes.

High-temperature ceramic- and carbon-matrix composites often use chemical vapor infiltration to achieve very high performance. The process is lengthy as a precursor gas must be transported into and product gases out of the interior of a fibrous "preform" to form the matrix. A preform design that provides rapid transport of gases would drop costs and speed up design cycles without a large decrease in mechanical properties. Independent of the constituent materials, composites manufacture is complicated by the very tailorability that is the hallmark of these materials. While high performance and manufacturability are by no means mutually exclusive, it is critical that the designer include processing considerations as part of the design cycle.

Introduction to Manufacturing and Design

Henry W. Stoll, Northwestern University

Introduction

THIS ARTICLE introduces and describes general concepts and practices related to manufacturing and design. It is intended to:

- Place the activities of design and manufacturing in the context of the business system that they support
- Present an overview of the manufacturing technology field from a design and material selection perspective
- Provide insight into the complex relationship among design, material selection, and manufacturing
- Summarize modern design for manufacture practices being widely used in industry today

The main focus is on how design and manufacturing practices influence the properties and cost of engineered designs. Engineered designs are products, equipment, devices, and hardware that have been designed to meet specific end-user needs. In this context, nuts and bolts, computers, electrical transformers, portable phones, automobiles, machine tools, construction equipment, consumer products, and aircraft are all engineered designs. In engineered designs, materials and methods of manufacture are typically selected to meet functionality, performance, cost, and reliability objectives.

Manufacturing can be defined as the conversion of starting materials into finished parts, products, and goods that have value to end users. Starting materials for engineered designs are very often semifinished products such as coil steel or pelletized plastic as well as "off-the-shelf" components and hardware. The specific starting material used for a particular part or product depends on the manufacturing process and on the types, variety, and availability of semifinished products that are acceptable for use in the process.

Manufacturing is both a technical activity and an economic activity. As a technical activity, manufacturing involves the design, development, implementation, control, operation, and maintenance of a large variety of manufacturing processes that facilitate and perform the conversion of starting materials into finished products having greater value. Processes used in manufacture can be grouped into two basic types: (1) physical and chemical processes that transform the shape, properties, and/or appearance of starting materials into parts, and (2) assembly and joining processes that combine multiple parts into finished products. In addition, there are myriad ancillary processes and operations that support the basic manufacturing processes in a variety of ways such as material handling, quality control, testing, and so on.

In the economic sense, manufacturing is a commercial activity performed by companies that sell products to customers. Hence, economic considerations are generally the overriding constraint in manufacturing decision making. The costs of energy, material, purchased components, labor, tooling, and capital equipment must be minimized and properly controlled if the firm is to make a profit. Producing and selling products is generally a very complex activity involving a convoluted mix of people skills and disciplines, machines and equipment, tooling, computers, and automation working together to form a manufacturing system. A manufacturing system comprises a large number of distinct functions and activities (Fig. 1) that interact in a variety of ways to ultimately produce and sell the product. On the business level, therefore, the challenge is to organize, optimize, and operate the manufacturing system in a way that ensures both long-term customer satisfaction and economic viability and success of the manufacturing enterprise.

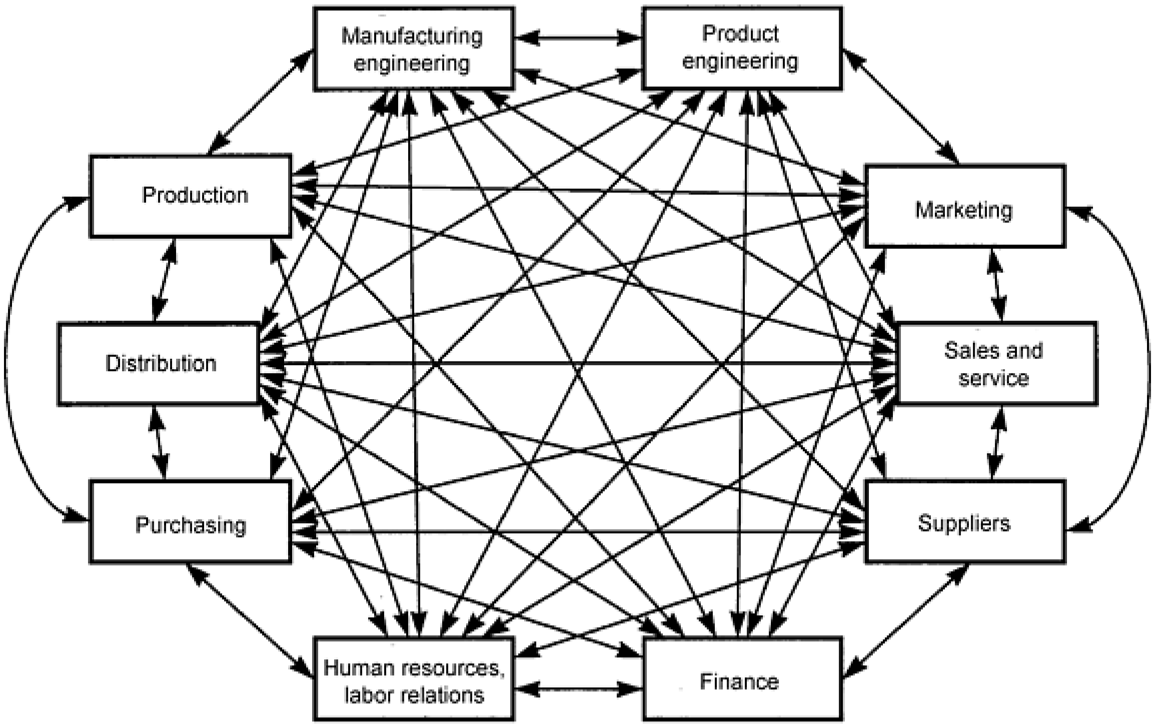

Fig. 1 The variety of ways the many different functions of a manufacturing system can interact

Introduction to Manufacturing and Design

Henry W. Stoll, Northwestern University

The Manufacturing Enterprise

Manufacturing usually is associated with a business activity or enterprise. To understand the relationship between manufacturing and business, consider the basic actions that occur when conducting a manufacturing-related business. Four groups of "main-line" work are generally necessary: decide what customers want, set up the factory to make it, produce it, and sell and service it. Tracing the "main-line" generic work flows that connect these activities yields two major cycles on which most design and manufacturing practices focus: the order-to-delivery cycle that involves the receipt of orders and production of existing products, and the new product introduction cycle that involves planning and introducing new products and changes into production.

The order-to-delivery cycle is the operations side of the business. It generates the day-to-day cash flow for the company by producing and distributing products, ensures product quality, and provides the interface between the company and its customers in the form of sales and service. The new product introduction cycle, on the other hand, is the product development, engineering, and new technology side of the business. For many businesses, product development and engineering is the life blood of the company. Effective new product development increases the company's competitive edge in everchanging markets.

At first glance, it may appear that these two cycles are independent of each other, but in fact they are very interrelated and closely coupled. This is because the new products introduced into production by product development must map into the production environment with the least amount of disruption and expense and in a way that ensures high product quality. This requires close coordination and cooperation between the product development and operations activities.

This mapping is one of the principal motivations for design for manufacture (DFM). Most engineered designs are assemblages of parts. Direct and indirect cost as well as quality of assemblies are determined by the number of parts; the ease with which the parts and components are handled, assembled, procured, and inspected; and the functionality, serviceability, maintainability, reliability, and durability achieved by the finished device or product.

All of these factors are in turn dependent on the material, manufacturing processes, and detail design of the individual parts and components that make up the finished assembly. Therefore, each part must be designed so that it not only meets functional requirements, but also can be manufactured and assembled economically and with relative ease in the production environment of the company. Effective part design requires early consideration of the characteristics, capabilities, and limitations of materials, manufacturing processes, and related operations, machinery, and equipment (including consideration of part-to-part variability, dimensional accuracy, surface finish, processing time, and so forth). These issues are discussed in greater detail in the article "Design for Manufacture and Assembly" in this Volume.

The type of production environment the design must map into drives many product design, material selection, and manufacturing decisions. This often leads to different manufacturing strategies. For example, one possible strategy is to assemble products using parts and components purchased from suppliers and vendors. In this approach, the manufacturer might pay more for individual parts and components, but avoid the direct and long-term indirect cost of making them internally and gain the advantage that the design team is relatively free to select materials and processes that best meet the functional needs of the new product.

On the other hand, if a manufacturer chooses to make many of the parts used in its products, that is, if it is "vertically integrated," then new products may need to be designed to be compatible with available "in-house" tooling and equipment. This can impose constraints on material and manufacturing process selection. For example, the cost and difficulty of introducing a spot-welded structure may be overwhelming for a company that has historically manufactured arc-welded structures. Similarly, switching to an all-plastic housing may prove difficult for a company that has traditionally made sheet metal housings and, as a consequence, has invested heavily in sheet metal forming equipment and expertise. In many product developments, "make or buy" decisions can strongly influence design direction; for many businesses, they can form the basis for business and manufacturing strategy.

New Product Introduction Cycle

The new product introduction cycle involves two major activities: tactical planning and product development. Tactical planning determines the "what" and "when" for product design and development and quantifies the needs that guide design and manufacturing. Product development translates the "what" into "how" by defining the new product designs to be introduced into production and providing the physical hardware, systems, information, training, and guidance to make new processes, tooling, and equipment work in production. Tactical planning is typically performed by marketing, advanced product planning, and technology development groups, while product development is typically performed by product engineering and manufacturing engineering groups.

Designing new products and introducing product changes takes time and costs money. If a new product takes too long to design and launch, the manufacturing enterprise can lose financially because of lost sales and market share. Even if the product gets to market in a timely manner or if time-to-market is irrelevant, the firm can lose financially if the cost of developing the design is excessive. The need to develop new products efficiently has led to several major trends in design and manufacturing practice.

Design Process Reengineering. Organizational and procedural changes have been made to enhance communication between functions, encourage DFM, and simplify and optimize work flow. Many companies have adopted concurrent engineering practices and are using the team approach effectively. In some cases, design and manufacturing engineering have been located on the same premises, while in other situations technologies such as teleconferencing, E-mail, and the World Wide Web are used to overcome wide geographical separations. Many companies are also working to improve their product realization process so that the design team knows exactly what to do during each step of the process. Gate or design reviews have been instituted to ensure economic viability of design projects and to facilitate simultaneous achievement of product manufacturability and tight schedule commitments. See Ref 1 for a comprehensive treatment of management aspects of product design.

Integrated Design Systems. Computer-aided design (CAD), computer-aided manufacturing (CAM), and computer-aided engineering (CAE) systems have been integrated so that product and manufacturing engineers work on compatible systems that share information in a seamless environment. In addition, a wide variety of new CAD tools and methods

have been introduced (see the Section "Design Tools" in this Volume), and their use has been made an integral part of the product realization process. Instead of computerizing manual practices such as drafting, design organizations are now using the computer to eliminate these practices where possible and to replace them with new computer-aided practices that reduce design time and effort. For example, parametric and feature-based CAD/CAM tools now enable design changes to be made and then propagated through the model with a few high-level commands. Using these tools, engineering analysis, manufacturing, and inspection can be automated and integrated with design to a higher degree than ever before.

Science Base. Traditionally, many engineered products have evolved and have been incrementally improved by using experimental or "test-and-fix" procedures involving costly and time-consuming construction and testing of many prototypes. This practice is being eliminated by developing a "science base" for the product technology involved. Once an appropriate science base is available, computer simulations and other analysis techniques can be used to more quickly select the best new design.

Product architectures are evolving that take advantage of commonalities present in different product models and variants. By modularizing and standardizing components and subsystems, creating building block parts, and rationalizing the variety of choices available for purchased components (such as threaded fasteners and ball bearings), many firms have greatly reduced design time for new products, especially those similar to existing products. These practices are also leading to significant savings of scope and scale. High-volume manufacturing processes and automation alternatives become economically feasible, and purchasing effort and the per part cost of supplied parts is reduced.

Taking time out of the product design cycle yields numerous benefits. Customer satisfaction is enhanced because improved product quality and short cycles give the customer what he wants when he wants it. Cost is reduced because waste and nonvalue activity is eliminated. Improved profitability results from increased market share combined with the ability to respond and adapt quickly to changing market conditions with minimum cost impact.

Order-to-Delivery Cycle

The order-to-delivery cycle typically involves three major activities: order fulfillment, production, and service. Order fulfillment is the sales arm of the business, responsible for bringing in orders for products and forecasting production requirements. Production converts sales orders into products. It encompasses all of the personnel, operations, processes, tooling, and equipment involved in the day-to-day manufacture of products including procurement, raw material and supplied component receiving and inspection, part manufacture, assembly, testing, and distribution of manufactured products. Service provides product-related maintenance, repair, disposal services, and support to the customer.

All of these activities influence design and manufacturing practices. For example, design for service and design for disassembly are important strategies in many companies. As another example, consider companies that sell specialized or customized products and services. These companies must often "quote" the job first, then manufacture and deliver the product or equipment after the order has been received. The time this process takes can contribute significantly to manufacturing lead time as well as strongly influencing customer satisfaction. Modular designs or designs that allow customization at the end of the production line help reduce order-to-delivery time for many of these types of customized products and equipment.

Marketing, manufacturing, and design strategy can also play an important role. Consider a company whose marketing strategy is to sell personal computers that are customized according to specifications provided by the customer via a phone order. Such a marketing strategy needs to be supported by a manufacturing strategy that facilitates easy manufacture and delivery of a customized product, together with a design strategy that makes the product easy to customize at remote distribution sites.

Another approach is to use computerization to take time out of the ordering process. One vision is that of a sales representative in the office of a customer with, for example, his or her portable computer having all product and pricing data available on disk, so that a complete purchase order or release can be negotiated on the spot and then inserted into the plant's production schedule by a modem and confirmed before the representative leaves the office.

An important measure of production efficiency and effectiveness is manufacturing lead time (MLT) or the time required to process the product through the plant. Manufacturing lead time is directly related to manufacturing cost and customer satisfaction. A short MLT implies less manufacturing time and labor and therefore lower manufacturing cost. Also, the

shorter the MLT, the sooner the product can be sold and the company reimbursed for its investment in raw material and labor. Most importantly, a short MLT means the customer gets the product when needed.

Reference 2 calculates MLT as,

$$\text{MLT} = \sum_{i=1}^{n_m} (T_{su} + QT_o + T_{no})_i$$

where n_m is the number of machines or operations and T_{su}, Q, T_o, and T_{no} are the setup time, batch quantity, operation time, and nonoperation time for each machine and/or operation, respectively. Nonoperation time includes handling, storage, inspections, and other nonvalue-added activities. Some manufacturing strategies given in Ref 2 that help reduce MLT and the order-to-delivery cycle are summarized in Table 1. These practices are often facilitated or made possible by design practices such as design for manufacture and assembly.

Table 1 Manufacturing strategies to reduce manufacturing lead time and the order-to-delivery cycle

Strategy	Effect[(a)]
1. Specialization of operations	Reduce T_o
2. Combined operations	Reduce n_m, T_h, T_{no}
3. Simultaneous operations	Reduce n_m, T_o, T_h, T_{no}
4. Integration of operations	Reduce n_m, T_h, T_{no}
5. Increase flexibility	Reduce T_{su}, MLT, WIP; increase U
6. Improve material handling and storage	Reduce T_{no}, MLT, WIP
7. On-line inspection	Reduce T_{no}, q
8. Process control and optimization	Reduce T_o, q
9. Plant operation control	Reduce T_{no}, MLT; increase U
10. Computer-integrated manufacturing	Reduce MLT, design time, production planning time; increase U

(a) T_h, work-handling time; WIP, work in process; q, scrap rate or fraction defect; U, utilization

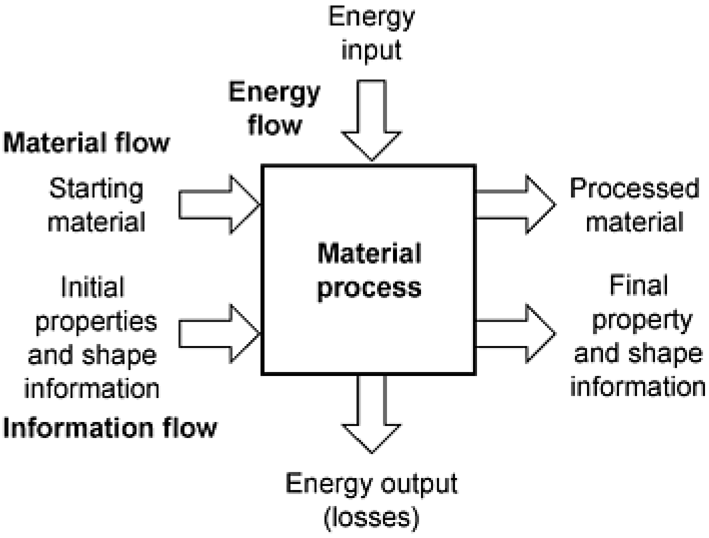
Manufacturing Processes

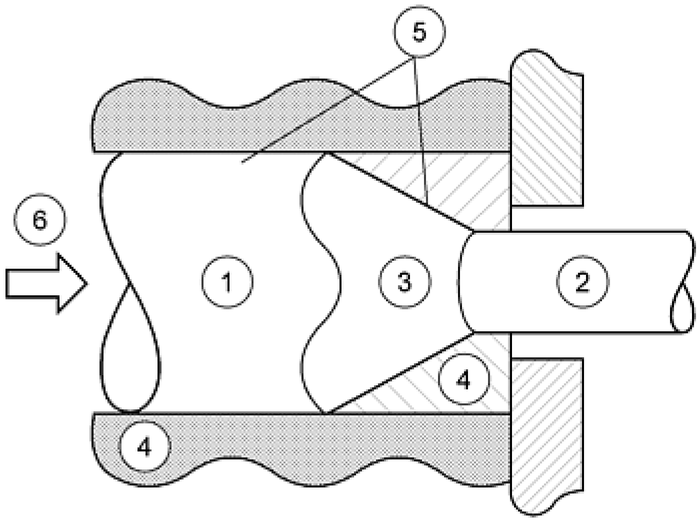
A general appreciation for the different manufacturing processes that are commonly used and for the design and manufacturing practices that are associated with them can be gained by considering the fundamental nature of manufacturing processes. A process can be defined as the change of properties of an object. Changes may concern geometry, hardness, strength, chemical composition, information content, and so forth. In general, three essential agents must be available to cause a change: energy, material, and information. Therefore, a process may be an energy process, a material process, or an information process. Most practical manufacturing processes are material processes.

A material process consists of a material flow on which shape information is impressed (information flow) and an energy flow that carries out the transformation of information through the tool/die and the pattern of movement for the tool/die and the material (Fig. 2). The energy flow includes both the energy necessary to carry out the process and the energy

output (loss) that is produced by the process. The information flow, which includes both shape and property information, depends on the nature of the material, the type of process (e.g., mechanical, thermal, chemical), the characteristics of the tool/die, and the pattern of movement of the material and the tool/die. The final geometry or shape information of the part is the sum of the initial shape information of the starting material and the shape information impressed on it by the process. Similarly, the final material properties of the part or product is the result of the property information of the starting material and the property change caused by the process. In general, the nature of a material process depends on whether the mass of the material is conserved, decreased, or increased.



(a)



(b)

(b) Schematic of one type of material process, bulk deformation by extrusion. 1, original material condition (shape and microstructure); 2, final material condition (shape and microstructure); 3, plastic deformation zone; 4, tooling effects; 5, friction effects; 6, equipment characteristics

Mass-Conserving Processes

In mass-conserving processes, the mass of the starting material is approximately equal to the mass of the final part or product. During the process, the starting material is "forced" to change its shape or properties in some way. Shape-replication processes are mass-conserving processes in which the part replicates the shape information stored in the die or mold by being forced to assume the shape of the surface of the tool cavity. Near-net-shape processes are shape-replication processes that produce parts requiring little or no subsequent processing (e.g., machining) to obtain the finished part. The nature and material requirements of shape-replication processes are generally determined by the state of the starting material.

Liquid or semifluid material is forced to flow into a mold cavity under pressure where it assumes the shape of the cavity. Hence, information is impressed primarily by the tool. However, most materials shrink as they solidify so the final geometry of the part is the sum of the tool shape plus distortions and dimensional changes due to material shrinkage. Representative processes include sand casting, die casting, and plastic injection molding. Process-related material considerations typically include melting temperature, flow behavior, ability of the material to assume the shape of the mold cavity, existing thermal and mechanical properties during solidification, resulting properties of the solidified material, and flaws such as porosity or voids that can occur as a result of the process.

Granular materials (metal powders, molding sand, etc.) are formed as a result of a flow process (filling, flow, placing) and a stabilization process (packing, plastic deformation, hardening, sintering, etc.). The geometry is primarily determined by the tool with some secondary geometry changes occurring due to shrinkage or forming occurring during stabilization. Representative processes include powder metallurgy and ceramics processing. Material considerations are process specific, but generally involve strength at various stages of the process, ability of the granular material to assume the desired shape, and density and final properties of the finished part.

Ductile Solid Materials. Forming takes place by plastic or elastic deformation of the starting material. The part shapes that are possible depend on the specific material, starting shape, and process to be used. In general, the material properties, the process parameters (state of stress, force, velocity, temperature, etc.) and the surface creation method must be analyzed together in order to establish the shape of the starting material, the tool design, and the process design. Representative processes include bulk deformation processes such as forging, extrusion, and rolling and sheet metal working processes such as stretching and drawing. Material considerations typically revolve around the ability of the material to flow plastically into the desired shape, property changes caused by plastic deformation, possible failure modes such as tears and splits, and dependency of mechanical properties on temperature and strain rate.

Near-net-shape processes are very desirable because little or no material is wasted and the final part can be produced quickly and consistently. However, large production volumes are often required to offset tooling cost. Design and manufacturing practice for mass-conserving processes generally focus on reducing tooling cost and development time and on setting process parameters to produce high-quality parts with low cycle times. Detail design of the part and material selection are of particular importance in these processes because the part features must be compatible with both the material properties and the manufacturing process.

Mass-Reducing Processes

A mass-reducing process is one in which the mass of the starting material is greater than the mass of the final part or product. Forming takes place by removal of material. Mass-reducing processes that alter the shape of the material are "shape-generation" processes because the part shape is determined by the pattern of relative motion between the cutting tool and the part. The starting material for mass-reducing processes is typically a ductile or brittle solid material. Methods of material removal include fracture, phase change such as melting or ablation, and chemical reaction. In general, material properties are not altered on a macroscopic level by mass-reducing processes. However, material properties are often a factor in determining processing speed and surface finish characteristics. The various processes that are commonly used can generally be classified according to the nature of the energy transfer medium or tooling used.

Conventional Machining Processes. In these processes, material is removed by fracture and the formation of chips created by relative movements between the workpiece material and the tool. In most conventional machining processes, the contour content of the tool is relatively small so the patterns of movement of the tool and workpiece material play a large role in the surface creation. The cutting tool can have a single cutting edge, such as the tool used in turning (lathe) or shaping operations, or it may have multiple cutting edges. Multiple-cutting-edge tools have either well-defined edge geometry such as milling cutters, drills, and saws, or randomly oriented cutting edges such as those in grinding wheels and abrasive paper.

Other Machining Processes. In these processes, material is removed by mechanical, thermal, electrical, and/or chemical action and often involve the use of granular, liquid, or gaseous media. In general, the surface creation is the result of the material removal mechanism, the geometry of the tool or cross section of the energy source, and the pattern of movement of the tool or energy source relative to the workpiece material. Examples include ultrasonic machining, electrical discharge machining (EDM), electrochemical machining (ECM), waterjet cutting, laser cutting, thermal cutting, and chemical etching.

Shearing processes involve separating adjacent parts of a sheet through controlled fracture. In some cases, such as punching, the material that is removed is scrap. In other cases, such as blanking, the material that remains is scrap. By varying the geometry of the tool and the pattern of movement, a large number of different processes are possible. Examples include punching, blanking, shearing, and slitting.

The complex patterns of movement required in machining processes typically result in excessive setup and cycle times. Hence, these processes are generally avoided if possible when large production quantities are involved. On the other hand, machining processes are capable of high precision and often they are the only option if tight tolerances are required. Also, because shape information is impressed through the pattern of movement rather than through the contour of the tool, machining is often the process of choice for low-volume manufacture where the cost of tooling must be kept low.

Design and manufacturing practices associated with mass-reducing processes generally focus on eliminating setup and processing time and on controlling process variation. For example, the use of numerical control (NC) makes it possible to change over from one part to another simply by downloading a different tool path program. CAD/CAM systems allow the rapid generation of the NC program directly from the solid model database. Also, by using modern sensor technology and feedback control techniques, NC systems can be designed to give extremely high accuracy and repeatability.

Assembly Processes

In mass-increasing processes, change is the result of the assembly or joining of components into a whole. Typically, the mass of the final part or product is approximately equal to the sum of the masses of the components. Assembly can be described as a series of joining processes in which parts are oriented and added to the build. The macrogeometry of the assembly is established by the positioning of the components. Joining processes are either permanent or nonpermanent and can be classified as shown in Fig. 3. Material properties and property changes produced by the process can be an important consideration in some joining processes such as solid-state and liquid-state welding.

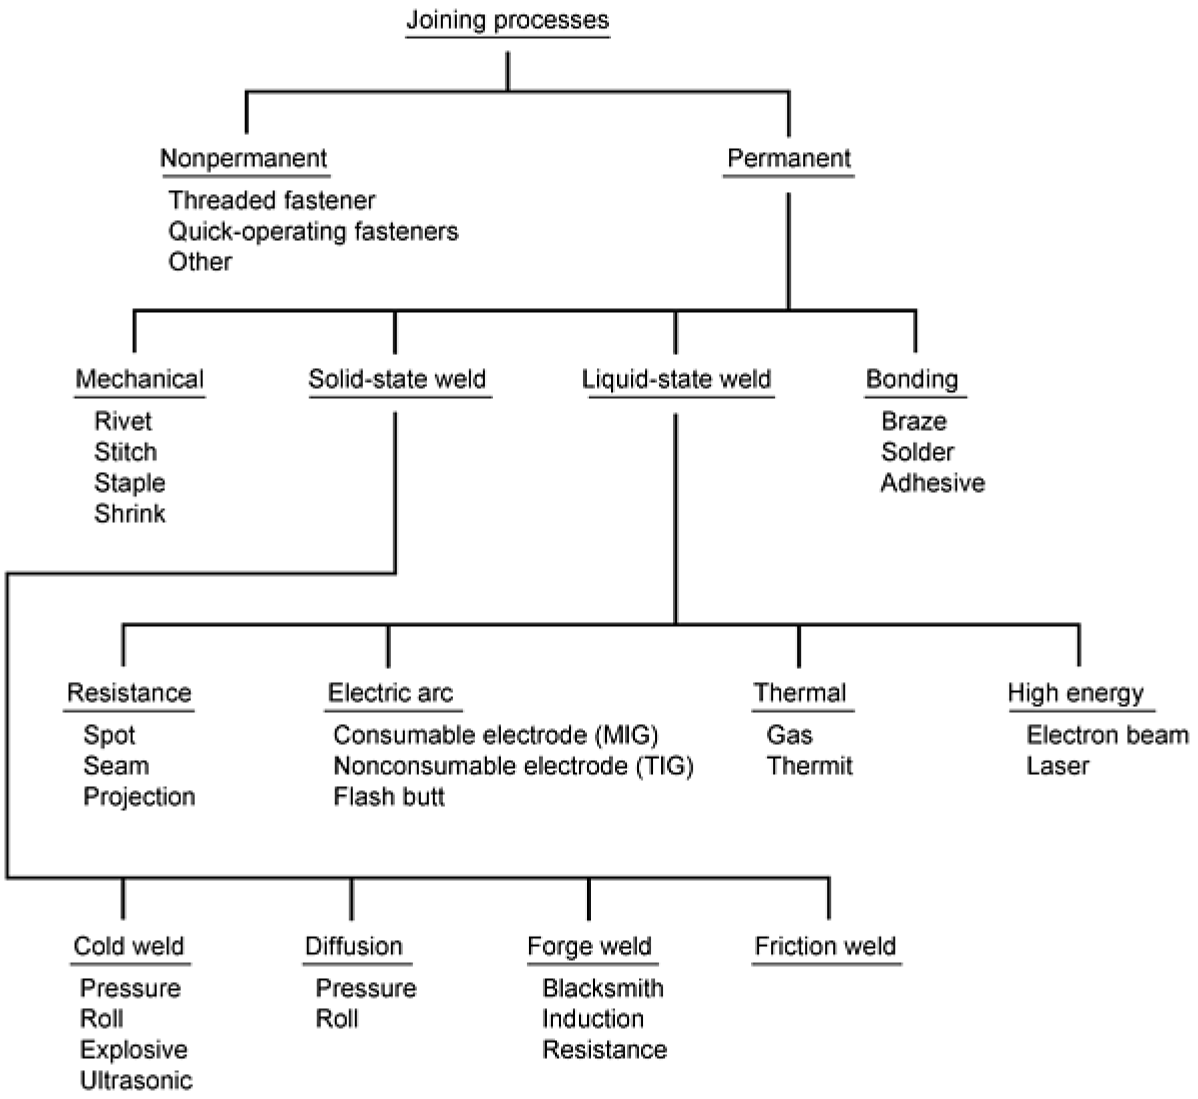


Fig. 3 Classification of joining processes (adapted from Fig. 9.1, in Ref 3). MIG, metal inert gas; TIG, tungsten inert gas

Assembly imposes constraints on the design. Not only must the parts be designed so that they can be assembled and joined together to provide the needed function, they must also be designed so that they are easy to handle, insert, retain, and verify that they have been assembled correctly. Because assembly is an integrative process, problems with detail part designs often surface when they are assembled. Parts do not fit together properly, tools cannot reach in the space provided, parts can be incorrectly assembled, and so forth. These problems can often require extensive rework resulting in costly schedule slippage and undesirable design compromises.

The importance of assembly as a design constraint has resulted in a greatly increased emphasis on assembly in the design process. Design and manufacturing practice now focuses on ensuring that parts conform to specifications, on eliminating variability and randomness from the process, and on making nonvalue-added operations such as orienting and handling as simple and easy to perform as possible. Many product design departments now use design for assembly techniques to improve the ease with which products are assembled. Design for assembly, which is discussed in detail in the article "Design for Manufacture and Assembly," which follows in this Volume, seeks to ensure ease of assembly by developing designs that are easy to assemble.

Many excellent textbooks on manufacturing processes and methods are available. See, for example, Ref 3, 4, and 5. Design issues related to specific processes are discussed in detail in the other articles in this Section of the handbook.

Production Systems

Manufacturing processes convert starting material into finished parts and products. Production systems link, coordinate, and integrate the various manufacturing processes used in production. Production systems are often designed and optimized to reduce manufacturing lead time, and as a result they may involve manual operations, mechanized operations, automated operations, or a mix of all three.

A distinction is generally made between mechanization and automation. According to Schey (Ref 3), mechanization means that something is done or operated by machinery and not by hand whereas automation means a system in which many or all of the processes involved in the production, movement, and inspection of parts and material are automatically performed or controlled by self-operating devices. Automation implies sensing, closed-loop control, and some degree of decision making in addition to mechanization. Flexible automation includes the added capability of being easily reprogrammed or adapted to meet varying or new production needs.

The kind of production systems used in modern factories depend greatly on the variety of products being produced and on production quantities. If production quantities are low and product variety is extensive, then the production systems are likely to be manual with an emphasis on accommodating variety. A glass blower who makes a wide variety of different ornamental decorations is an example. In this case, the glass blower probably does his or her work at one workbench with all needed tools readily at hand. He or she is ideally set up to make individual pieces, one at a time, and in any order necessary to meet customer demand.

At the other extreme, if production quantities are large and only one product is made, it is likely that dedicated mechanization or automation would be used. For example, a company that makes millions of a certain type of lightbulb each year is likely to manufacture the lightbulb using a production machine that is fully automated but capable of producing only that one particular type of lightbulb. Figures 4 and 5 depict the relationship among product complexity, production volume, and level of automation.

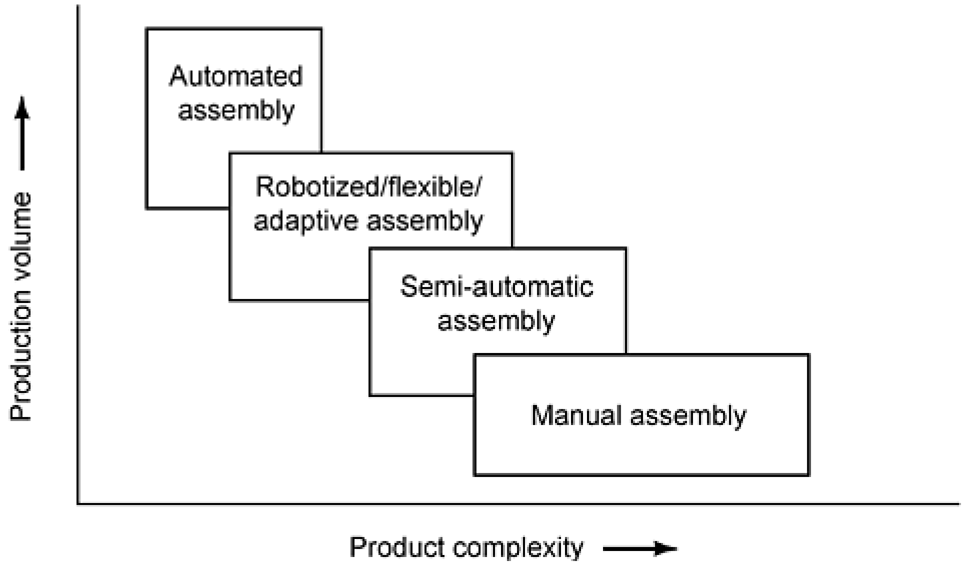

Fig. 4 Production volume versus product complexity. Source: Ref 6

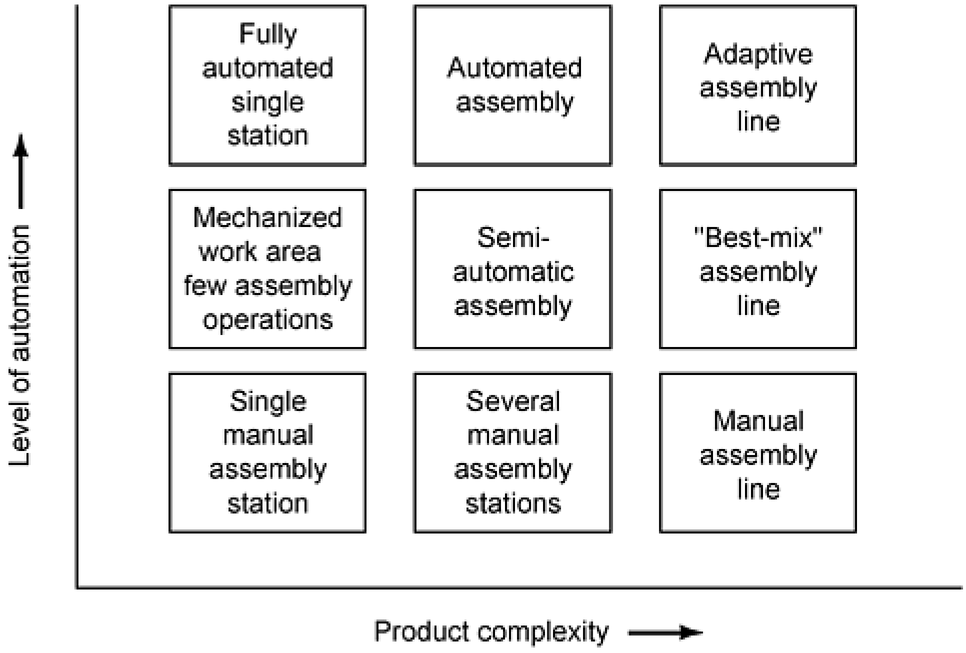

Fig. 5 Level of automation versus product complexity. Source: Ref 6

Although production systems are not of direct concern in material selection, they do impact part and product design in a variety of ways. For example, if a part is to be bowl fed, it must be properly designed for that environment. This implies that the material must hold up under bowl feeding conditions. Similarly, if a part is to be handled by a robot, it must have the appropriate design features that allow gripping and it must be capable of withstanding the gripping forces involved. Production systems therefore often superimpose additional constraints on design and material selection. Leading-edge companies that manufacture products in large quantities often utilize a "design for automation" approach in which the needs of the production system are considered very early in the product design and the systems integrator or supplier of the automation equipment is an important member of the concurrent engineering team.

Interaction between Design and Manufacturing

The design of a product and its method of manufacture are intimately connected. This interdependence cuts across all aspects of the manufacturing system and exists at the part, assembly, and system levels of product design and manufacturing. The interaction between design and manufacturing is easiest to see at the part level. Suppose, for example, that a part is to be designed as a casting. If the part is to be manufactured using a casting process, then a material suitable for the particular casting process being considered must be selected. This material must also have suitable functional properties such as strength, corrosion resistance, weight, and so forth. Given a specific material and casting process, the part must then be properly designed to satisfy both functional and processing requirements. This means that not only must the finished part have a certain desired shape and set of material properties, it must also have an acceptable parting line, sufficient draft, and a geometry that facilitates proper solidification of the material to achieve the desired material properties without porosity and other flaws.

The interaction between design and manufacturing at the assembly level should be one of ease and simplicity. How a product is assembled is determined by its design. If assembly is considered as part of design, then many potential difficulties and quality risks can usually be avoided. If assembly is not considered, manufacturing will still find a way to assemble the product, but the cost of assembly as well as indirect cost is likely to be higher and product quality may suffer.

Design and manufacturing interactions are perhaps hardest to delineate, quantify, and control at the systems level, and yet it is at this level that these interactions have the most long-term impact and far-reaching consequences. Consider, for example, the sheet metal used in making an automobile. From the design point of view a wide selection of different sheet metal thicknesses, roll widths, coatings, and material properties is desirable so that the most optimal design can be achieved with respect to structural rigidity, weight, and cost. From the manufacturing point of view, however, the ability to process a wide selection of different thicknesses and types of sheet metal means added cost and complexity in purchasing and supplier relations, material handling and storage, processing equipment and tooling, setups and operations, and so forth. What is needed is the right balance that gives design the flexibility it needs while still allowing manufacturing the ability to simplify and standardize its operations. How a company manages interactions such as this can greatly affect its long-term economic viability and competitiveness.

Introduction to Manufacturing and Design

Henry W. Stoll, Northwestern University

Design for Manufacture Practices

The interaction between design and manufacture has resulted in a variety of design and manufacturing practices. This section provides a brief overview of various practices that are of general importance to design and manufacturing. Some of these practices, such as standardization and group technology, span several organizations within a company and have their greatest effect at the systems level. Others, such as design for assembly, focus on the interaction between design and specific manufacturing processes. Still others, such as failure mode and effects analysis and value engineering, can be used at all levels and in all contexts to improve both product design and the method of manufacture. Related coverage is provided in the Sections "The Design Process" and "Criteria and Concepts in Design" in this Volume.

Design for life-cycle manufacturing is a philosophy of product design that includes the full range of policies, techniques, practices, and attitudes that cause a product to be designed for the optimal manufacturing cost, the optimal

achievement of manufactured quality, and the optimal achievement of life-cycle support (serviceability, reliability, and maintainability). This philosophy is often implemented by companies that perceive product design to be a competitive advantage. The concepts of design for assembly, concurrent engineering (see the article "Concurrent Engineering" in this Volume), and other systematic design approaches that cause the design team, from the outset, to consider all elements of the product life cycle from conception through disposal are all considered to be part of this general, overarching philosophy. The philosophy is implemented both through the product realization process utilized within the company and through the general culture and attitudes embodied by the company employees.

The design for assembly (DFA) method was developed by Geoffrey Boothroyd while at the University of Massachusetts (Amherst). Details of the methodology are presented in Ref 7. Design for assembly is also discussed in detail in the article "Design for Manufacture and Assembly" in this Volume. Based largely on industrial engineering time-study methods, the DFA method seeks to minimize the cost of a product within constraints imposed by other design requirements. This is done by first reducing the number of parts and then ensuring that the remaining parts are easy to assemble.

Design for "X" (DFX) Methods. A variety of "design for" methods and approaches are being developed and used to improve the designs of parts and products with respect to specific manufacturing processes and activities. Examples of methods aimed at manufacturing activities include design for service, design for testing, design for disassembly, and so forth. Design for casting, design for plastic injection molding, and design for machining are examples of DFX methods directed toward improving the design of parts that are to be manufactured using a specific manufacturing process. Many companies have specialized manufacturing facilities that can only process parts or assemblies that have acceptable characteristics such as part spacing or size. Guidelines, developed by manufacturing engineers who are very familiar with the capability of the specific facility for use by design engineers, is another example of a DFX methodology. Design for "X" methods seek to provide guidance to the designer that helps ensure that parts and products are correctly designed to be compatible with a given process or activity. Benefits include lower tooling costs, reduced process cycle times, and improved process yields.

Design for Quality. Variability is the enemy of manufacturing. It is a major cause of poor quality resulting in unnecessary manufacturing cost, product unreliability, and ultimately, customer dissatisfaction and loss of market share. Variability reduction and robustness against variation of hard-to-control factors are therefore recognized as being of paramount importance in the quest for high-quality products. In a design for quality approach, the design team seeks to design the product and process in such a way that variation in hard-to-control manufacturing and operational parameters is minimal. The ideas behind this approach are largely attributable to the efforts of G. Taguchi and the cost-saving approaches to quality control pioneered in Japan. An important element of this approach is the extensive and innovative use of statistically designed experiments. The Taguchi method and other design for quality approaches are described in the articles "Robust Design" and "Design for Quality" in this Volume, and they are treated extensively in the literature (see, for example, Ref 8).

Process-Driven Design. In process-driven design, a method of assembly or other manufacturing process plan is developed prior to developing the product design. This plan is then used to guide the product design thereby ensuring a coordinated product and process that results in an optimization of the overall manufacturing system. Process-driven design is based on the recognition that product design decisions often inadvertently limit the manufacturing options available for use in production of the product. Process-driven design methods have been successfully applied in many different industries. For example, many of the modern innovative manufacturing and assembly methods now commonly used in the automotive, airplane, and farm machinery industries can be traced to process-driven design practices.

Failure mode and effects analysis (FMEA) is an important design and manufacturing engineering tool intended to help prevent failures and defects from occurring and reaching the customer. It provides the design team with a methodical way of studying the causes and effects of failures before the design is finalized. Similarly, it helps manufacturing engineers identify and correct potential manufacturing and/or process failures. In performing a FMEA, the product and/or production system is examined for all the ways in which failure can occur. For each failure, an estimate is made of its effect on the total system, its seriousness, and its frequency of occurrence. Corrective actions are then identified to prevent failures from occurring or reaching the customer. The great value of FMEA lies in its systematic approach in analyzing product and/or process performance in critical detail. Also, interaction between manufacturing and design engineering required while conducting a FMEA can be very effective in helping to ensure product and process conformance at an early stage of design. A more complete discussion of the FMEA approach is provided in several other articles in this Volume and in Ref 9.

Value engineering provides a systematic approach to evaluating design alternatives that is often very useful and may even point the way to innovative new design approaches or ideas. Also called value analysis, value control, or value management, value engineering uses a multidiscipline team to analyze the functions provided by the product and the cost of each function. Based on results of the value analysis, where value is the ratio of function and cost, creative ways are sought to eliminate waste and undesired functions and to achieve required functions at the lowest possible cost while optimizing manufacturability, quality, and delivery. Value engineering is very broad in scope. A disadvantage of the value engineering approach is its reliance on cost data that often cannot be accurately determined until after design decisions have been made. This can detract from its usefulness as a tool for enhancing the quality of early design decisions. On the other hand, when used properly, value analysis can be a very useful tool for helping to make material and process selection decisions. Value engineering is widely discussed in the literature (see Ref 10, for example). See also the article "Value Analysis in Materials Selection and Design" in this Volume.

Standardization. This practice seeks to limit and/or reduce manufacturing information content of products by eliminating specials and standardizing wherever possible. Information content of the product and quality risks are reduced when part variations (e.g., in the types of screws used) are kept to a minimum. It is seldom justifiable, for example, to use several screw sizes or drive styles in one assembly. Minimizing part variations also simplifies manufacturing by reducing the information content of the production system required to produce the part. Substitution of standard (off-the-shelf) components in place of special-purpose designs helps reduce part variations as well as total information content of the manufacturing system. A stock item is always less expensive than a custom-made item. Standard components require little or no lead time and are more reliable because characteristics and weaknesses are well known. They can be ordered in any quantity at any time. They are usually easier to repair and replacements are easier to find. Use of standardized components puts the burden on the supplier and makes the supplier do more.

Standardization and rationalization (S&R) is a combined design and business approach or philosophy that specifically targets reduction of part proliferation companywide. In essence, S&R seeks to further leverage the benefits of standardization by minimizing the number of standard parts used. In the S&R approach, *standardization* is defined as the reduction in number of different parts used in current and former designs. *Rationalization* is the identification of the fewest number of parts required for use in future designs. Such an approach is ideal for material selection. Consider, for example, a company that buys a large variety of different thermoplastic materials. In the S&R approach, each of these different plastic materials would be evaluated with respect to volume purchased per year, required properties, and other relevant considerations. Based on this evaluation, a "rationalized" list is developed that is agreed upon by design and manufacturing personnel as being sufficient. Thermoplastic materials used in all new designs are then selected from this short list. Over time, the number of different materials used by the company decreases, saving time and money. Less time is needed to select materials, and product and process development time is reduced because the materials are well understood within the company. Money is saved because fewer materials are bought in higher volume from established suppliers.

Group Technology (GT) is an approach to design and manufacturing that seeks to reduce manufacturing system information content by identifying and exploiting the sameness or similarity of parts based on their geometrical shape and/or similarities in their production process. Group technology is implemented by using classification and coding systems to identify and understand part similarities and to establish parameters for action. Manufacturing engineers use GT to decide on more efficient ways to increase system flexibility by streamlining information flow, reducing setup time and floor space requirements, and standardizing procedures for batch-type production. Design engineers use GT to reduce design time and effort as well as part and tooling proliferation. With increasing emphasis on flexible and integrated manufacturing, GT is also an effective first step in structuring and building an integrated database. Standardized process planning, accurate cost estimation, efficient purchasing, and assessment of the impact of material costs are benefits that are often realized. A more complete discussion of GT, especially as it applies to manufacturing, is given in Ref 11.

Design for Manufacture and Assembly

Geoffrey Boothroyd, Boothroyd Dewhurst, Inc.

Introduction

DURING THE 1980s AND 1990s, the United States has been losing millions of dollars per day to its foreign competitors. Competitiveness has been lost in many areas, but most notably in automobile manufacture, as highlighted by a worldwide study of this industry that was published in 1990 (Ref 1). The study, which showed that Japan had the most productive plants at that time, attempted to explain the wide variations in automotive assembly plant productivity throughout the world. It was found that automation could only account for one-third of the total difference in productivity among plants worldwide and that, at any level of automation, the difference between the most and least efficient plants was enormous.

The authors of the study concluded that no improvements in operation can make a plant fully competitive if the product design is defective. There is now overwhelming evidence to support the view that product design for manufacture and assembly can be the key to high productivity in all manufacturing industries.

Design for Manufacture and Assembly

Geoffrey Boothroyd, Boothroyd Dewhurst, Inc.

Introduction to Design for Manufacture and Assembly

It has long been advocated that designers should give attention to possible manufacturing problems associated with a design. Traditionally, the idea was that a competent designer should be familiar with manufacturing processes to avoid adding unnecessarily to manufacturing costs. Until the 1960s, the supposed solution in education was to provide "shop" courses to familiarize engineering students with the ways products are manufactured. However, even this approach has now been abandoned by the colleges because the courses lacked academic content. Furthermore, with the increasingly complex technology incorporated within many products, the time pressures put on designers to get designs onto the shop floor, the "we design it, you manufacture it" attitude of designers, and the increasing sophistication of manufacturing techniques, designers have become less and less able to avoid unnecessary manufacturing costs.

Since the early 1980s, it has become recognized that more effort is required to take manufacturing and assembly into account early in the product design cycle. One way of achieving this is for manufacturing engineers to be part of a simultaneous or concurrent engineering design team.

Within this teamworking, design for manufacture and assembly (DFMA) software analysis tools help in the evaluation of proposed designs. It is important that design teams have access to such tools in order to provide a focal point that helps identify problems from manufacturing and design perspectives.

Use of DFMA software allows a systematic procedure that aims to help companies keep the number of component parts in an assembly to a minimum and make the fullest use of the manufacturing processes that exist. It achieves this by enabling the analysis of design ideas. It is not a design system, and any innovation must come from the design team. However, it does provide quantification to help decision making at the early stages of design.

Figure 1 summarizes the steps taken when using DFMA software during design. The design-for-assembly (DFA) analysis is conducted first, leading to a simplification of the product structure. Then, early cost estimates for the parts are obtained for both the original design and the new design in order to make trade-off decisions. During this process, the best materials and processes to be used for the various parts are considered. For example, would it be better to manufacture a cover from plastic or sheet metal? Once the materials and processes have been finally selected, a more thorough analysis for design for manufacture (DFM) can be carried out for the detail design of the parts.

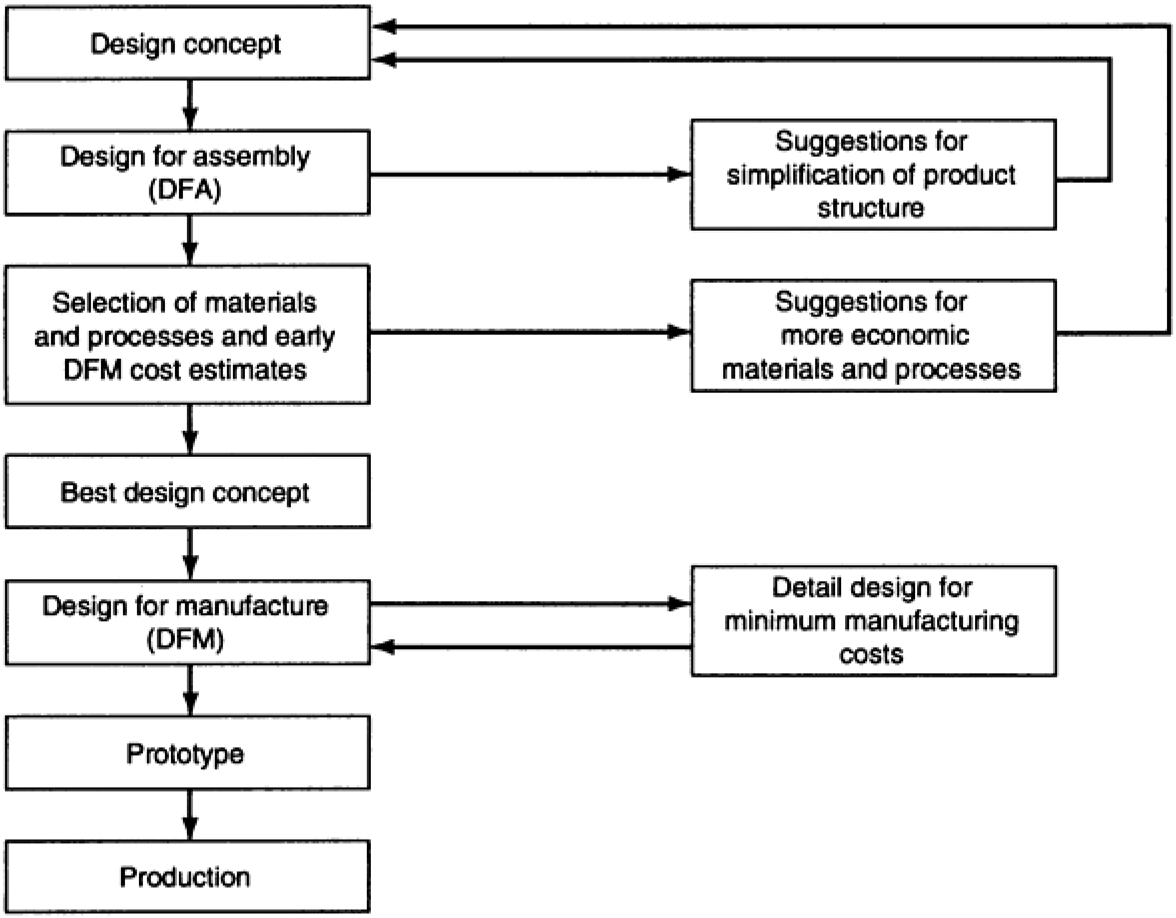

Fig. 1 Typical steps taken when using DFMA software in design

It should be remembered that DFMA is the integration of the separate but interrelated design issues of assembly and manufacturing processes. Therefore, there are two fundamental aspects to producing efficient designs: DFA to help simplify the product and quantify assembly costs and the early implementation of DFM to quantify parts cost and allow trade-off decisions to be made for design proposals and material and process selection.

Design for Assembly

The DFA analysis tool was developed by the author in the mid-1970s. The idea was to stress the economic implications of design decisions. This is crucial, because while design is usually a minor factor in the total cost of a product, the design process fixes between 70 and 95% of all costs.

The author and his colleague, Peter Dewhurst, developed a personal computer program for DFA that was first introduced in 1982. Since then, the DFA database of time standards has been expanded to include the assembly of large products, cable harnesses, and printed circuit boards.

Reducing the number of separate parts, thereby simplifying the product, is the greatest improvement provided by DFA. To give guidance in reducing the part count, the DFA software asks the following questions as each part is added to the product during assembly:

- Is the part or subassembly used only for fastening or securing other items?
- Is the part or subassembly used only for connecting other items?

If the answer is "yes" to either question then the part or subassembly is not considered theoretically necessary. If the answer is "no" to both questions the following criteria questions are then considered.

- During operation of the product, does the part move relative to all other parts already assembled?
- Must the part be of a different material than, or be isolated from, all other parts already assembled? Only fundamental reasons concerned with material properties are acceptable.
- Must the part be separate from all other parts already assembled because the necessary assembly or disassembly of other separate parts would otherwise be impossible?

If the answer to all three criteria questions is "no," the part cannot be considered theoretically necessary.

When these questions have been answered for all parts, a theoretical minimum part count for the product is obtained. It should be emphasized, however, that this theoretical minimum does not take into account practical considerations or cost considerations, but simply provides a basis for an independent measure of the quality of the design from an assembly viewpoint.

While answering these minimum part questions, the design team is challenged to justify the existence of each separate part and this is where brainstorming usually results in considerable product simplification. In fact, it is found from more than 70 published case studies that the average reduction in the number of parts is 50% as a result of using the DFA software.

Estimating Assembly Time. The next step is to estimate the assembly time for the product design and establish a DFA index in terms of difficulty of assembly.

To estimate assembly time, each part in the design is examined for two considerations: how the part is to be acquired (fetched if necessary), oriented, and made ready for insertion; and how it is inserted and/or fastened into the product.

The difficulty of these operations is rated, and from this rating standard times are determined for all the operations necessary to assemble each part. The DFA time standard is a classification of design features that affect part assembly. It is a system for use in product design similar to the standard time systems used by industrial engineers such as MTM, WorkFactor, or MOST and was developed from 12 years of industry and university experiments. Usage has proved the data to be quite accurate for the overall times that are generally within 6% of the actual times.

For estimation of the handling time the designer must specify the symmetry of the item, its major dimension, and its thickness. In addition, the designer must specify whether the item nests or tangles when in bulk, whether it is fragile, flexible, slippery, sticky, and whether it needs two hands, grasping tools, optical magnification, or mechanical assistance in the form of cranes.

A portion of the database for estimation of the time for insertion of small items is shown in Fig. 2. Here it is important to know whether the assembly worker's vision or access is restricted, and whether the item is difficult to align or insert. Other portions of the database deal with resistance to insertion, and whether the item requires holding down in order to maintain its position for subsequent assembly operations.

		Easy to align and insert	Not easy to align or insert	Not easy to align and insert	Severe difficulties
		0	1	2	3
No access or vision difficulties	0	1.5	3	4.5	7.5
Obstructed access or restricted vision	1	3.7	5.2	6.7	9.7
Obstructed access and restricted vision	2	5.9	7.4	8.9	11.9

Fig. 2 Portion of database of manual insertion times (in seconds) without fastening for small parts where no holding down or regrasping is required. Copyright Boothroyd Dewhurst, Inc.; used with permission

For fastening operations, further questions may be required. For example, the type of tool used for threaded fasteners and the number of revolutions required are important in a determination of the total fastening time. A further consideration relates to the location of the items that must be acquired. If turning, bending, or walking are needed to acquire the item, a different database for acquisition and handling is used.

Thus, for each classification of handling and insertion, an average time is given leading to an estimate of the total manual assembly time for an item.

Design Efficiency (Ease of Assembly). When all the items and operations for assembly of a product have been analyzed, the total assembly time for the product can be estimated, and using standard labor rates, so can assembly costs. Also, the efficiency of a design from an ease of assembly point of view can be determined; this is the DFA index.

Based on the assumption that all of the critical parts could be made easy to assemble--requiring only about 3 s each--the minimum assembly time is equal to the theoretical minimum number of parts times three. The assembly efficiency percentage or DFA index is equal to the minimum assembly time divided by the estimated total assembly time multiplied by 100.

The maximum value of the DFA index is 100%. However, excellent designs can have a DFA index much lower. For example, good designs of small electromechanical assemblies have values of around 20%. Thus, much depends on the type of assembly and, with experience, the values that are achievable in different circumstances will be known.

At the DFA stage, part manufacturing costs are not brought into the analysis, but the DFA index and the estimated assembly times provide benchmarks against which further design iterations, previous estimates for an original product design, or a competitor's product can be compared.

Other Assembly Analysis Methods

Assemblability Evaluation Method (AEM). The AEM method, described in 1986 by Miyakawa and Ohashi (Ref 2), uses two indices at the earliest possible stage of design, namely the assembly-evaluation score, E, which is used to assess the design quality or the difficulty of assembly, and the assembly-cost ratio, K, which is used to project assembly costs relative to current assembly costs. The method does not distinguish between manual, robot, or automatic assembly, because according to Myakawa and Ohashi there is a strong correlation between the degrees of assembly difficulty using these three methods.

In the AEM, approximately 20 symbols represent the various assembly operations. Each symbol has an index to assess the ability to assemble the part under consideration. Examples of the symbols and penalty scores are given in Table 1, and examples of their application are given in Table 2.

Table 1 Examples of AEM symbols and penalty scores

Elemental operation	AEM symbol	Penalty score
Downward movement[(a)]	↓	0
Soldering	S	20

Table 2 Examples of assemblability evaluation and improvement

Product structure	Assembly operations	Ability to assemble part evaluation score	Ability to assemblability evaluation score	Assembly cost ratio	Part to be improved
	1. Set chassis	100	73	1	Block
	2. Bring down block and hold it to maintain its orientation	50			
	3. Fasten screw	65			
	1. Set chassis	100	88	~0.8	Screw
	2. Bring down block (orientation is maintained by spot facing)	100			
	3. Fasten screw	65			
	1. Set chassis	100	89	~0.5	Block
	2. Bring down and press fit block	80			

Assembly-Oriented Product Design. Some ten years after the introduction of the Hitachi AEM and the Boothroyd Dewhurst DFA methods, variations started to appear. One of the first was that of Warnecke and Bassler at the University of Stuttgart, Germany. In their assembly-oriented product design method (Ref 4), they assess the usefulness or functional value of each part. Thus, both assembly difficulty and functional value are evaluated, and a combined rating is given. This means that parts that have little functional value (such as separate fasteners) and that are difficult to assemble are given the lowest ratings. These ratings are then used as guides to redesign (see Fig. 3).

Assembly procedure	FM	AM	KM
Insert receiver base in readiness	13.20	5.5	2.4
Insert holder for receiver cap in receiver base	1.48	16.5	0.09 ←
Insert holder for microphone in receiver base	1.48	16.5	0.09 ←
Insert microphone in receiver base	25.14	8.5	2.958
Insert receiver cap in receiver base	19.93	8.5	2.345
Clamp receiver cap and microphone with holder	1.82	31.0	0.059 ← (Threshold level)
Insert antikink device in receiver base, mount cable	6.30	202.5	0.031 ←
Lock receiver top in position	14.40	12.5	1.152
Screw receiver base to receiver top	2.13	43.0	0.049 ←

KM scale: 0 0.5 1.0 1.5 2.0 2.5 3.0 3.5

FM, functional content of procedure; AM, assembly expenditure; KM, characteristic value of procedure (KM = FM/AM). Characteristic value of subassembly (*K*) is 0.250. Arrows denote weak technical aspect of assembly. Source: Ref 4

Lucas Method. The Lucas method was developed at the University of Hull, United Kingdom, during the late 1980s (Ref 5). In the Lucas method, three steps are followed, as described below.

Step 1: Functional Analysis. Parts are categorized into A parts (demanded by the design specification) and B parts (required by that particular design solution). A target is set for design efficiency, which is A/(A + B) and is expressed as a percentage. The objective is to exceed an arbitrary 60% target value by the elimination of category B parts through redesign. The Lucas method authors emphasize assembly-cost reduction and parts-count reduction and include the use of the present author's minimum-parts criteria in a "truth" table to assist in part-count reduction.

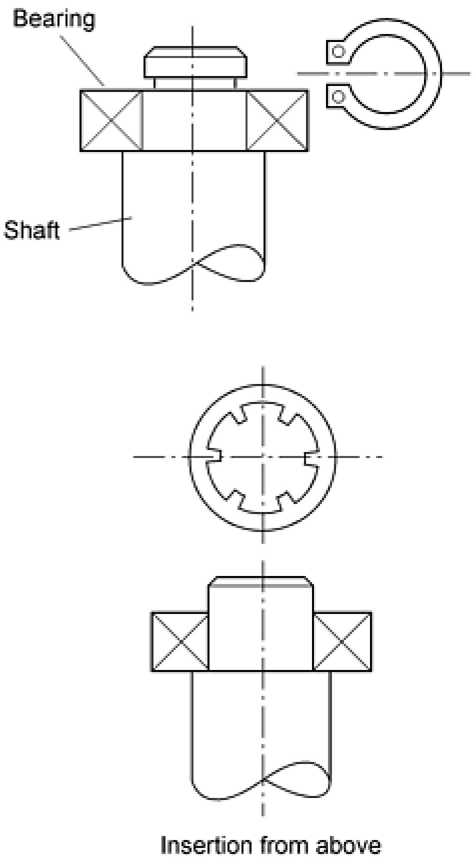
Step 2: Handling and Feeding Analysis. The parts are scored on the basis of three factors: the size and weight of the part, handling difficulties, and the orientation of the part. The score is summed to give the total score for the part, and a handling/feeding ratio is calculated that is given by the total score divided by the number of A parts. A target of 2.5 is recommended.

Step 3: Fitting Analysis. Based on the proposed assembly sequence, each part is scored on the basis of whether it requires holding in a fixture, the assembly direction, alignment problems, restricted vision, and the required insertion force. The total score is divided by the number of A parts to give the fitting ratio. Again, it is recommended that this ratio approach 2.5 for an acceptable design.

DAC Method. Sony Corporation claims to have developed a unique set of rules for increased productivity involving design-for-assembly cost effectiveness (DAC). Yamigawa (Ref 6) reiterates the view that it is impossible to design for assembly ease unless one starts at the time of conception before the blueprint for the product is drawn up. The improvement of a design at its inception is referred to as the concept of feed-forward design, as opposed to making improvements later with feedback from the manufacturing process.

In the DAC method, factors for evaluation are classified into 30 key words. The evaluations are displayed on a diagram using a 100-point system for each operation, thus making judgment at a glance easy. A list of operations is presented on the DAC diagram, and a bar is drawn that represents the score for that particular operation (Fig. 4). Operations with low

scores are easily identified. Since 1987, DAC has been introduced in various companies in Japan and overseas. Emphasis is given to the ease with which an operation can be carried out automatically, and the method is used to illustrate problems with the efficiency of the assembly system.



Before improvement

Core operation			DAC	50
Shaft press fit	P		80	
Bearing press fit	T		90	
C-ring			30	
Screw tightening			90	
			80	

After improvement

Core operation			DAC	50
Shaft press fit	P		80	
Bearing press fit	T		90	
O-ring			90	
Screw tightening			90	
			80

Design for Manufacture (DFM)

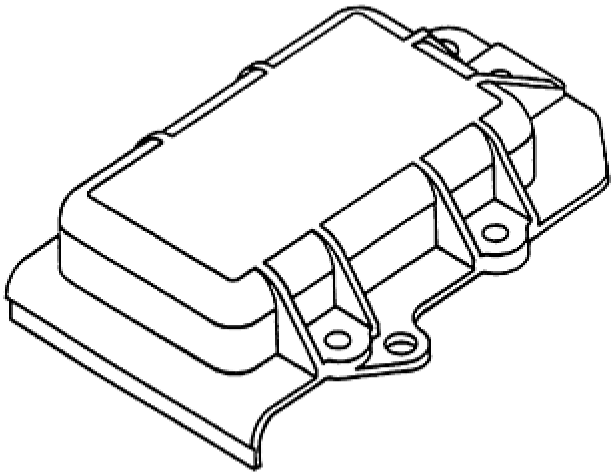
Design for assembly has generated a revolution in design practices, not principally because it usually reduces assembly costs, but because it has a far greater impact on the total manufacturing costs of a product. The reason is that DFA simplifies the product structure, reduces the number of parts, and thereby reduces the total cost of the parts. However, to judge the effects of DFA at the early design stage, companion methods for the early estimation of part costs must be made available, and accordingly, many of those who have developed DFA methods are now turning their attention to methods of assessment of part-manufacturing difficulties.

For example, the Hitachi researchers (Ref 7) have introduced a machining producibility evaluation method, which combined with their AEM, gives an overall producibility-evaluation method (PEM).

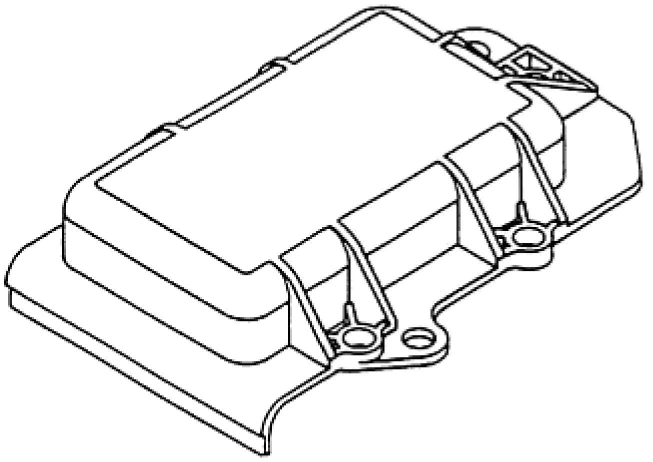
Similarly, Toshiba Corporation (Ref 8) has developed a processability evaluation method, which combined with other methods, including an assemblability-evaluation method, provides an overall producibility-evaluation method. Processability is defined as being proportional to the cost of the part. The cost of the part is determined by the selection of the part-processing method, and then by the design of the part shape. Various processing methods are considered for a particular part. The cost of the part is then determined for all combinations of the selected processing methods and suitable materials. Then the design of the part is evaluated to see whether it fits a particular processing method, and finally, a processability evaluation is carried out.

Since 1985, the author and his colleagues Dewhurst and Knight have developed methods for designers to obtain cost estimates for parts and tooling during the early phases of design. Studies have been completed for machined parts (Ref 9), injection-molded parts (Ref 10), sand-cast, investment-cast and die-cast parts (Ref 11, 12, 13), sheet-metal stampings (Ref 14), and powder-metal parts (Ref 15). The objective of these studies was to provide methods with which the designer or

design team can quickly obtain information on costs before detailed design has taken place. For example, an analysis (Ref 16) of an injection-molded heater cover gave the results shown in Fig. 5. It was evident that certain wall thicknesses were too large, and that, through some fairly minor design changes, the processing cost could be reduced by 33%. If these studies had taken place at the early design stage, the designer could also have considered the cost for an equivalent sheet-metal part, for example. In fact, the use of these analysis techniques is now allowing designers and purchasing managers to challenge suppliers' estimates. In one example, it has been reported that Polaroid Corporation has saved $16,000 to $20,000 on the cost of tooling for an injection-molded part (Ref 17).



Heater core cover (polypropylene-20% talc)



Redesigned cover with cored pads

Manufacturing factor	Existing design	Redesign
Cost of one cavity and core	$8,032	$11,625
Cycle time, s	42.8	13.3
Number of cavities required	6	2
Cost of production mold	$36,383	$22,925
Cost per part[(a)]	$0.251	$0.168

(a) Includes $0.05 for material

Fig. 5 Design-for-manufacture analysis of injection-molded heater cover. Source: Ref 16

Early Cost Estimating. The problem of estimating part and tooling costs before the part has been fully detailed is discussed using machining as an example because this is one of the most common shape-forming processes. Several conventional cost estimating methods for machining are available both in handbook form, such as the *Machining Data Handbook* (Ref 18) and the *AM Cost Estimator* (Ref 19) and in software form. However, all of these methods are meant to be applied after the part has been detailed and its production has been planned, and they are not tailored for use by a designer. During the early stages of design, the designer will not wish to specify, for example, all the work-holding devices and tools that might be needed--a detailed design will not yet be available. Indeed, a final decision even on the work material might not have been made.

For early cost estimating an important assumption has to be made. The designer should be able to expect that, when the design is finalized, care will have been taken to avoid unnecessary manufacturing expense at the detail-design stage and that manufacturing will take place under efficient conditions.

To illustrate how such an assumption can help in providing reasonable estimates, consider the effect of the metal-removal rate on grinding costs, as shown in Fig. 6. These cost curves indicate that as the removal rate is increased the cost of grinding-wheel wear increases in proportion. At the same time, the cost of grinding decreases because the grinding cycle is shortened; in fact, the grinding costs are inversely proportional to the removal rate.

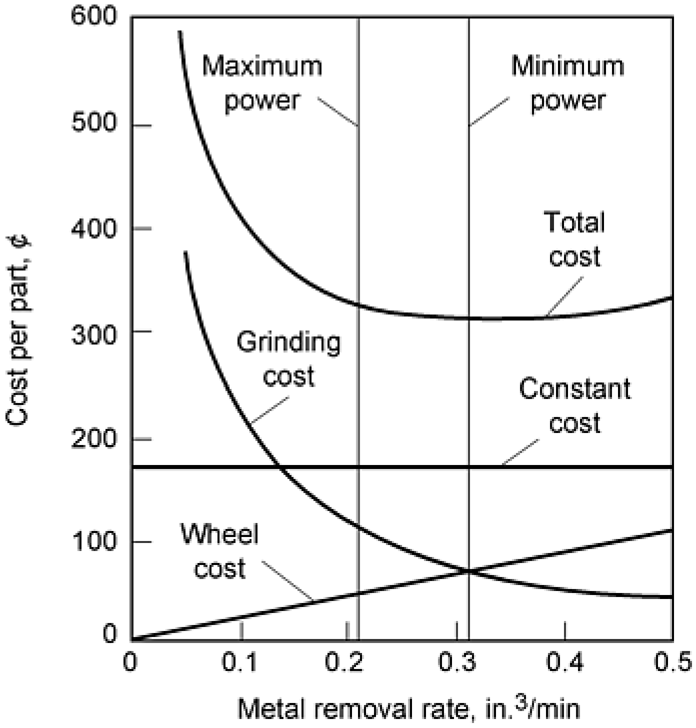


Fig. 6 Effect of metal removal rate on grinding costs

Under these circumstances, it is easy to show that the minimum cost condition occurs when the grinding costs and wheel costs are equal. Hence, we can say that if economic grinding conditions are used in the manufacture of a part, wheel costs can be allowed for by doubling the estimated grinding costs. Even if economical conditions cannot be used--say, because of power limitations--it is still possible to adjust the grinding costs to allow for wheel costs. This simple example illustrates the general approach to early cost estimating.

In estimating machining costs, perhaps the simplest method would be to specify the shape and size of the original workpiece and the quantity of material to be removed by machining. An estimate could then be made of the material cost needed to manufacture the part, and if an approximate figure were available for the average cost of removal of each unit volume of material by machining, an estimate could also be made of the machining cost. Even the tool-replacement costs could be allowed for.

Unfortunately, this very simple approach does not account for the nonproductive costs associated with a series of machining operations. For example, if a small volume of material were to be removed in a single pass by a turning operation, the nonproductive costs would be relatively small. In this case, the part needs only to be loaded into the lathe and subsequently unloaded once. Compare this with the same volume of material removed by a sequence of operations, on different machines, for example: turning, threading, milling, and drilling. The nonproductive costs accumulate and become a significant factor in the ultimate cost of the machined part, especially for small parts.

Principal Cost Drivers. The principal factors in estimating machining costs for a particular part are:

- The amount of material removed (directly affects the material cost per unit volume of the finished part and the rough-machining time)
- The cost of using the machine tools and operators
- The power available for machining and the specific cutting energy (unit power) of the work material
- The nonproductive times--especially for smaller parts, for which they may become the most significant factors
- The surface area to be finish-machined
- The recommended finish-machining conditions, which are affected by the work material and tool material used and the surface roughnesses and tolerances required

Provided that values are available for the various material and machine-tool factors, the most time consuming aspects of applying the model are estimating the total quantity of material removed and the total surface area to be finished-machined. In fact, an estimate of the volume of material removed would probably be made by calculating the volumes removed by individual cutting operations. Similarly, the total surface area to be finish-machined is made up of the areas of the surfaces generated by individual cutting operations.

Clearly, if the dimensions of individual cuts must be specified, it is no additional effort for a computer to calculate the individual rough-machining and finish-machining times for each cut, making proper allowance for tool material, recommended conditions, machine-tool characteristics, and individual nonproductive times.

Thus, although experience shows that acceptable early cost estimates can be obtained using the model described above, in a computer implementation of the process it is more sensible to specify each volume or area element and to estimate the appropriate machining time and cost. This procedure has an added advantage: the results indicate the relative cost of each design feature, indicating to the designer where manufacturing costs might be reduced.

The importance of this is illustrated in the following example where a product design is analyzed for ease of assembly (DFA) as well as manufacture costs of the individual parts (DFM).

Example: Application of DFMA Software to the Design of a Motor-Drive Assembly.

Figure 7 shows the requirements of a motor-drive assembly that must be designed to sense and control its position on two steel guide rails. The motor must be fully enclosed for aesthetic reasons and have a removable cover for access so that the position sensor can be adjusted. The principal requirement is a rigid base that is designed to slide up and down the guide rails and that supports the motor and sensor. The motor and sensor have wires that connect them to a power supply and a control unit, respectively.

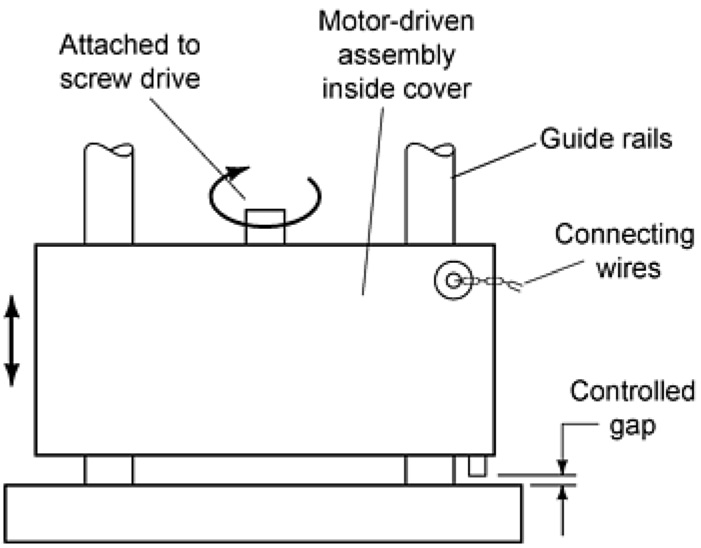

Fig. 7 Motor-drive assembly design requirements

A proposed solution is shown in Fig. 8. The base is provided with two bushings to provide suitable friction and wear characteristics. The motor is secured to the base with two motor screws, and a hole in the base accepts the sensor, which is held in place with a set screw. To provide the required covers, an end plate is secured by two end-plate screws to two standoffs, which are, in turn, screwed into the base. This end plate is fitted with a plastic grommet through which the connecting wires pass. Finally, a box-shaped cover slides over the whole assembly from below the base and is held in place by four cover screws, two passing into the base and two into the end cover.

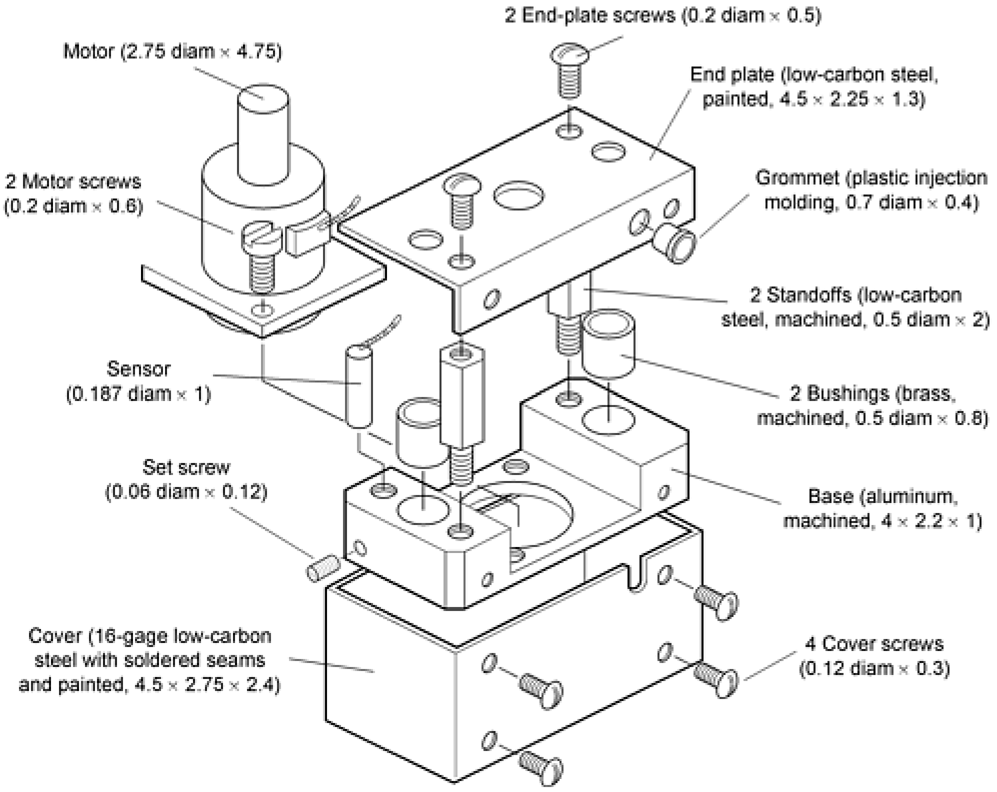

Fig. 8 Initial design of motor-drive assembly. Dimensions in inches

Two subassemblies are required, the motor and the sensor, and in this initial design there are eight additional main parts--and nine screws--making a total of 19 items to be assembled.

The application of the minimum part criteria to the proposed design proceeds as follows:

- The base is assembled into a fixture, and because there are no other parts with which to combine it, it is a theoretically necessary part.
- The two bushings do not satisfy the criteria and can theoretically be integral with the base.
- The motor is a standard subassembly of parts that is a purchased item. Thus, the criteria cannot be applied unless the assembly of the motor itself is considered as part of the analysis. In this example, it is assumed that the motor and sensor are not to be analyzed.
- Invariably, separate fasteners such as the two motor screws do not meet the criteria, because an integral fastening arrangement is always theoretically possible.
- The sensor is a purchased item.
- The set screw is theoretically not necessary.
- The two standoffs do not meet the criteria; they could be incorporated into the base.
- The end plate must be separate for reasons of assembly.
- The two end-plate screws are theoretically not necessary.
- The plastic grommet can be of the same material as, and therefore combined with, the end plate.
- The cover can also be combined with the end plate.
- Finally, the four cover screws are theoretically not necessary.

From this analysis, it can be seen that, if the motor and sensor subassemblies can be arranged to snap or screw into the base, and a plastic cover can be designed to snap on, only four separate items will be needed, instead of 19. These four items represent the theoretical minimum number needed to satisfy the constraints of the product design without consideration of the practical limitations.

It is now necessary for the designer or design team to justify the existence of those parts that have not satisfied the criteria. Justification may arise from practical, technical, or economic considerations. In this example, it can be argued that the two motor screws are needed to secure the motor, and the set screw is needed to hold the sensor, because any alternatives would be impractical for a low-volume product such as this.

It can be argued that the two powder metal bushings are unnecessary, because the base could be machined from an alternative material with the necessary frictional characteristics. Finally, it is very difficult to justify the separate standoffs, end plate, cover, grommet, and associated six screws.

Before an alternative design can be considered, it is necessary to have estimates of the assembly times and costs, so that any possible savings can be taken into account when considering design alternatives. Using DFMA time standards and knowledge bases, it is possible to make estimates of assembly costs, and then to estimate the cost of the parts and associated tooling, without having final detail drawings of the parts.

First, Table 3 shows the results of the DFA analysis, where it is seen that the total assembly time is estimated to be 160 s. It is also possible to obtain a measure of the quality of the design for ease of assembly. The theoretical minimum number of parts is four and, if these parts were easy to assemble, they would take about 3 s each to assemble on average. Thus, the theoretical minimum (or ideal) assembly time is 12 s, a figure that can be compared with the estimated time of 160 s, giving a DFA index of 12/160, or 7.5%.

Table 3 Results of DFA analysis for initial design of motor-drive assembly shown in Fig. 8

Part	No.	Theoretical part count	Assembly time, s	Assembly cost, ¢
Base	1	1	3.5	2.9
Bushing	2	0	12.3	10.2
Motor subassembly	1	1	9.5	7.9
Motor screw	2	0	21.0	17.5
Sensor subassembly	1	1	8.5	7.1
Set screw	1	0	10.6	8.8
Standoff	2	0	16.0	13.3
End plate	1	1	8.4	7.0
End-plate screw	2	0	16.6	13.8
Plastic bushing	1	0	3.5	2.9
Thread leads	. . .	. . .	5.0	4.2
Reorient	. . .	. . .	4.5	3.8
Cover	1	0	9.4	7.9
Cover screw	4	0	31.2	26.0
Totals	**19**	**4**	**160.0**	**133.0**

DFA index = (4 × 3)/160 = 7.5%

The elimination of parts not meeting the minimum part-count criteria, and that cannot be justified on practical grounds, results in the design concept shown in Fig. 9. Here, the bushings are combined with the base, and the standoffs, end plate, cover, plastic bushing, and six associated screws are replaced by one snap-on plastic cover. The eliminated items entailed an assembly time of 97.4 s. The new cover takes only 4 s to assemble, and it avoids the need for a reorientation. In addition, screws with pilot points are used and the base is redesigned so that the motor is self-aligning. Table 4 presents the results of a DFA analysis of the redesigned assembly. The new assembly time is only 46 s, and the DFA index has increased to 26%. Assuming an assembly labor rate of $30 per hour, the savings in assembly cost amount to $0.95.

Table 4 Results of DFA analysis for redesign of motor-drive assembly shown in Fig. 9

Part	No.	Theoretical part count	Assembly times, s	Assembly cost, ¢
Base	1	1	3.5	2.9
Motor subassembly	1	1	4.5	3.8
Motor screw	2	0	12.0	10.0
Sensor subassembly	1	1	8.5	7.1
Set screw	1	0	8.5	7.1
Thread leads	. . .	. . .	5.0	4.2
Plastic cover	1	1	4.0	3.3
Totals	**7**	**4**	**46.0**	**38.4**

DFA index = (4 × 3)/46 = 26%

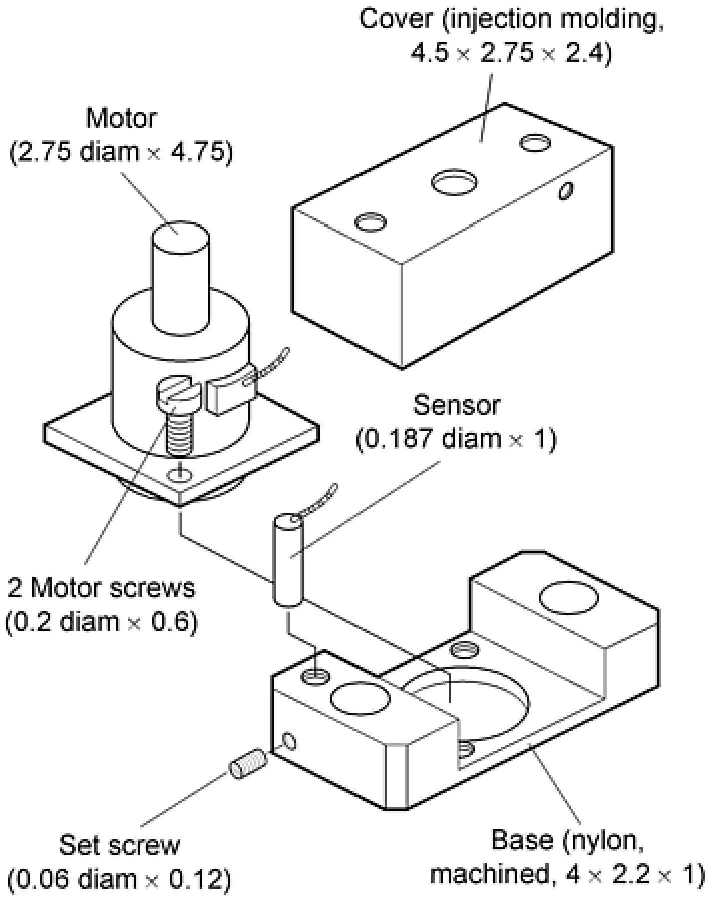

Fig. 9 Redesign of motor-drive assembly following DFA analysis. Dimensions in inches

Table 5 presents the results of DFM cost analyses of the parts for the two designs. There were five machined parts included in the original design. Their manufacturing costs were estimated using the machining cost estimating software. For small quantities, the standoffs cost $4.87 each and the bushings $1.53. Because these items are eliminated in the proposed redesign, a direct savings of $12.80 results.

Table 5 Comparison of part costs for motor-drive assembly initial design and redesign

Item	Cost, $
Initial design (Fig. 8)	
Base (aluminum)	15.29
Bushing (2)	3.06
Motor screw (2)	0.20[a]
Set screw	0.10[a]
Standoff (2)	9.74
End plate	2.26
End-plate screw (2)	0.20[a]
Plastic bushing	0.10[a]
Cover	3.73
Cover screw (4)	0.40
Total (initial design)	**35.08**
Redesign (Fig. 9)	
Base (nylon)	13.04
Motor screw (2)	0.20[a]
Set screw	0.10[a]
Plastic cover	8.66[b]
Total (redesign)	**22.00**

(a) Purchased in quantity.

(b) Includes tooling cost for plastic cover ($8000)

The costs of the cover and end plate were estimated using the sheet metalworking software and assuming the use of a turret press. The cover cost was $3.73 and the end plate cost was $2.26, giving a total of $5.99. These items are replaced by a snap-on cover which, using the injection molding software was estimated to cost $8.66 for a total production of 1000. This figure includes tooling costs of $8000.

The shape of the base remains essentially unchanged for the redesigned motor assembly. However, it is now machined from nylon instead of aluminum, in order to eliminate the bushings. The effect of the change in material was to reduce the cost from $15.29 to $14.78 because the savings in material costs (nylon $0.49 compared to aluminum $2.34) more than offset increases in machining costs. However, in the conceptual redesign several drilled and tapped holes are eliminated reducing the cost of the base by a further $1.74 to $13.04. It might be noted that this saving alone is greater than the savings in assembly cost, emphasizing that it is important for the designer to estimate the cost of individual features on a machined component when considering various design proposals.

In conclusion, the example DFMA analysis of the motor assembly has shown a possible savings of $14.03, taking the cost of assembly and the cost of the eliminated screws and plastic bushing into account.

Design for Manufacture and Assembly

Geoffrey Boothroyd, Boothroyd Dewhurst, Inc.

Results of DFMA Applications

DFMA software provides a systematic procedure for analyzing proposed designs from the point of view of assembly and manufacture. This procedure results in simpler and more reliable products that are less expensive to assemble and manufacture. In addition, any reduction in the number of parts in an assembly produces a snowball effect on cost reduction, because of the drawings and specifications that are no longer needed, the vendors that are no longer required, and the inventory that is eliminated. All of these factors have an important effect on overhead costs, which in many cases, form the largest proportion of the total product cost.

DFMA tools encourage dialogue between designers and the manufacturing engineers and any other individuals who play a part in determining final product costs during the early stages of design. This means that teamworking is encouraged, and the benefits of simultaneous or concurrent engineering can be achieved. The following selection of published case studies illustrates the results of DFMA applications.

Application of DFMA at an Electronics Manufacturer. The portable-products division of Motorola designs and manufactures portable radios for the landmobile-radio market. This includes such users as police and firemen, in addition to those in the construction and utility fields. DFMA methods have been used to simplify these products and reduce assembly costs (Ref 20).

The results of the first redesign efforts were so encouraging (Table 6) that Motorola surveyed several products that had been redesigned using the DFA methodology to see if there might be a general correlation of assembly efficiency with manufacturing quality. Figure 10 shows what they found. The defect levels are reported as defects per million parts assembled, which allows a quality evaluation to be made that is independent of the number of parts in the assembly. Each result in Fig. 10 represents a product with an analyzed assembly efficiency (DFA index) and a reported quality level.

Table 6 Results from redesign of vehicular adaptor for a portable radio

Item	Old product	New product	Change, %
DFA index	4	36	800
Assembly time, s	2742	354	87
Assembly count	217	47	78
Fasteners	72	0	100

Source: Ref 20

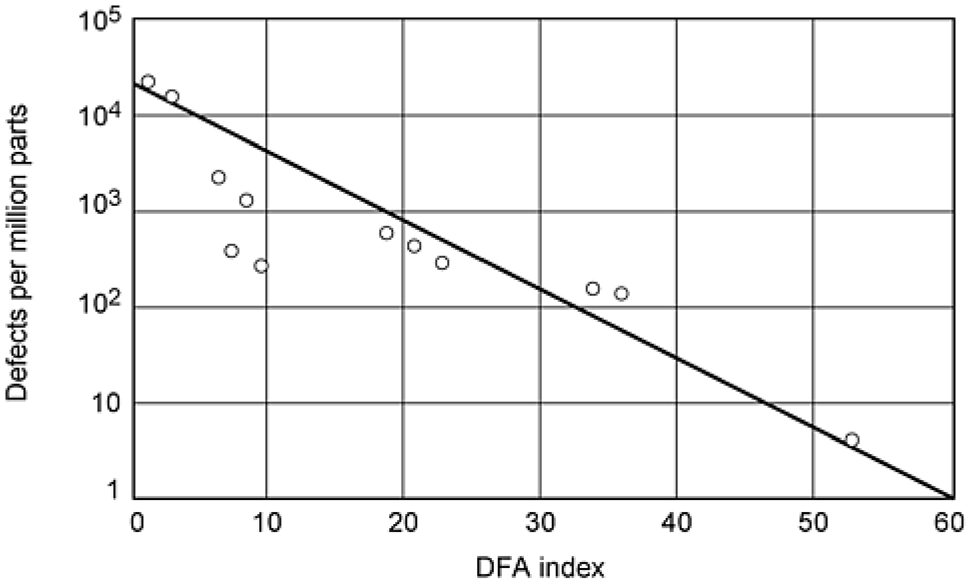

Fig. 10 Correlation between DFA index and part defects for an electronics manufacturer. Every 1 s of assembly penalty time (from DFA analysis) causes an average of 100 defects per million parts. Source: Ref 20

Design-for-Assembly Implementation at an Automotive Manufacturer. Ford Motor Company has trained thousands of its engineers in the DFA methodology and requires its vendors to conduct DFA analysis prior to submitting bids on subcontracted products. This is not surprising, when Ford reported savings of more than $1 billion annually as a result of applying DFMA to the original Taurus line of cars.

The following example of the procedures for implementation of DFA comes from Ford Motor Company's Transmission and Chassis (T&C) Division (Ref 21).

- Provide DFA overview for senior management.
- Choose DFA champion/coordinator.
- Define objectives.
- Choose pilot program.
- Choose test case.
- Identify team structure.
- Identify team members.
- Coordinate training.
- Have first workshop.

During the workshop:

- Review the parts list and processes.
- Break up into teams.
- Analyze the existing design for manual assembly.
- Analyze the teams' redesigns for manual assembly.
- Teams present results of original design analysis versus redesign analysis.
- Prioritize redesign ideas A, B, C, and so forth.
- Incorporate all the A and B ideas into one analysis.
- Assign responsibilities and timing.

The combined results of the initial workshops held in the T&C Division of Ford indicated potential assembly labor savings of 29%, a reduction in part count of 20%, and a reduction in the number of operations of 23%.

Enormous cost benefits have been gained since the introduction of the DFA methodology in the T&C Division. Even more importantly, the changes resulting from DFA have brought substantial quality improvements. Moreover, the design lead time has been reduced by one-half and is expected to be halved again.

Manufacturability Benchmarking by an Automotive Manufacturer. A few years ago, General Motors (GM) made comparisons between its assembly plant for the Pontiac at Fairfax, Kansas, and Ford's subassembly plant for its Taurus and Mercury Sable models near Atlanta, Georgia. General Motors found that there was a large productivity gap between its plant and the Ford plant. General Motors concluded that 41% of the producibility gap could be traced to the manufacturability of the two designs. For example, the Ford car had many fewer parts (ten in its front bumper compared with 100 in the GM Pontiac), and the Ford parts fitted together more easily. The GM study found that the level of automation, which was actually much higher in the GM plant, was not a factor in explaining the productivity gap.

The subsequent application of DFMA can be seen in select areas of the 1992 Cadillac Seville and Eldorado (Ref 22). For example, the new bumper system reduced part count by half over the previous generation, and assembly time was about 19 min less than the pre-DFMA design. A further example was the Cadillac console. In this case a reduction of 40% in assembly time and a 33% reduction in part count was achieved by employing DFMA from the concept stage.

Application of DFMA at a Toy Manufacturer. Toy manufacturers must comply with some of the most demanding time-to-market schedules of any industry. With an average product life cycle of only one year, toys are serious business for the development teams in the promotional division of one of the largest toy companies in the world, Hasbro, Inc.

One case where DFMA software has cut redesign time and cost is for a toy fire truck (Ref 23). For example, the original ladder assembly was composed of 33 metal parts and subassemblies, with an assembly time of 198 s. The redesigned ladder brought the number of parts down to its theoretical minimum of only five parts--all plastic--with an assembly time of just 22 s.

Hasbro also has found that DFMA provides a nonthreatening way to get team members talking about a design without anyone feeling as though others are encroaching on his or her territory. It also allows Hasbro's tooling and manufacturing engineers to get involved at the concept stage, eliminating any surprises.

Application of DFMA at a Medical Devices Manufacturer. At Respironics Inc., Pennsylvania, DFMA software enables engineering teams to define goals at the earliest stages of product design and then manage priorities as the project progresses (Ref 24). This firm designs, manufactures, and markets medical devices used to treat respiratory and cardiopulmonary disorders.

A design team used DFMA in the early design stages of a manual resuscitator to make the product easier to manufacture and assemble and to improve the overall design process as well. Executives began the product-development project by establishing a team of engineering, product-development, and management personnel. The team evaluated customer requirements and created early product specifications. At this time, a multifunctional project team was also formed with representatives from key suppliers, engineering, purchasing, design-drafting, manufacturing, production and quality assurance, and accounting. According to the DFMA facilitator (Ref 24), the project benefited greatly from DFMA brainstorming sessions, and the most valuable success factor was how the process of DFMA focused the team on its objectives. The team created the vision of the product, all members had an early sense of ownership and what the product was going to be, and they challenged themselves to make it work.

The following table shows the improvements for the new design over the previous product:

Factor	Improvement
Assembly time	84%
Assembly cost	74%
Number of unique parts	65%
Total number of parts	66%
Number of operations	81%

The new product is greatly simplified. No separate fasteners or lubricants are used; the previous design used both. All parts snap or press fit together, with one heat-stake operation and one adhesive-bond joint. In addition, the adhesive joint is being redesigned to eliminate the adhesive.

The project produced innovative features and approaches that generated patent applications for six claims--all developed during the initial DFMA workshop.

Application of DFMA at an Aerospace Manufacturer. In 1991, the U.S. Navy presented McDonnell Douglas with a challenge: produce an aircraft to carry them into the 21st century. The company responded with a proposed new version of their FA-18 Hornet fighter jet (Ref 25).

One of the most direct ways DFMA helped reduce costs and improve quality was to force designers to reduce the number of parts and fasteners used in the aircraft. For each fastener there is the chance that a hole will either be drilled in the wrong place or be the wrong size. By reducing the number of parts and fasteners, the opportunity for defects is reduced.

Weight is also a critical aspect of aircraft design. There are 179,000 fasteners in the Hornet. A commercial transport like the MD-11 can have 1,300,000. Reference 26 explains how weight can be systematically reduced through part count reduction strategies. If two sheet metal parts are to be attached, they usually require a flange on one of them to allow space for a row of rivets or fasteners. This adds weight in the form of extra metal and the extra fasteners. By producing the two parts as one machined piece, the weight is reduced. When this principle is applied to an entire aircraft, overall weight reduction is very significant.

Other results of using DFMA were realized throughout the new aircraft design. In the previous model, several parts were made of multiple sheet metal components because machined parts were unable to reach minimum gage limits. With high-speed machining, however, the thinner gage limits became possible. One example: the nose barrel bulkhead--one of several large walls in the forward section of the aircraft between the cockpit and the nose radar dome--previously consisted of 90 separate parts. The redesigned one-piece wall in the new model cost $3746 less and cut 20 days from production time.

The Navy and McDonnell Douglas named the new model the Super Hornet. Rolled out on time and within budget, the Super Hornet was 25% larger than the previous version, yet it contained 42% fewer parts. It weighed in at 1000 lb under the Navy's weight specification and flew farther, with more payload, than its predecessor. Originally scheduled for first flight in December 1995, the first complete Super Hornet successfully took to the sky 32 days early, in November.

Roadblocks in Implementation of DFMA

The above examples have shown that the format for successful implementation of DFMA varies from company to company, but some major points stand out. First, DFMA software is a team tool and should be utilized as such.

Training is important. Implementation of DFMA efforts employ the software system, and for this reason some companies believe it is, for example, similar to using a spreadsheet program. This is not the case. It is important to train people in a workshop environment--a team using the system on an ongoing project with the company's "champion" or an outside system consultant providing help. In this way, one or two days provides useful training plus, often as not, real results. It is important to remember that it is often not the target, but the journey through the systematic procedure, that matters.

Experience has shown that there are many barriers to the implementation of DFMA. Reasons for resisting the implementation of DFMA are often put forward, but all can be answered.

Lack of Time. The most common complaint among designers is that they are not allowed sufficient time to carry out their work. Designers are usually constrained by the urgent need to minimize the design-to-manufacture time for a new product. However, more time spent in the initial stages of design will reap benefits later in terms of reduced engineering changes after the design has been released to manufacturing. Company executives and managers must be made to realize that the early stages of design are critical in determining not only manufacturing costs, but also the overall design-to-manufacturing cycle time.

"Not Invented Here" Syndrome. Enormous resistance can be encountered when new techniques are proposed to designers. Ideally, any proposal to implement DFMA should come from the designers themselves. However, more frequently it is the managers or executives who have heard of the successes resulting from DFMA and demand that their own designers implement the philosophy. Under these circumstances, great care must be taken to involve the designers in the decision to use these new techniques.

"Ugly Baby" Syndrome. Even greater difficulties exist when an outside group or a separate group within the company undertakes to analyze existing designs for ease of manufacture and assembly. Commonly, this group will find that significant improvements could be made to the original design, and when these improvements are brought to the attention of those who produced the design, this can result in extreme resistance. Telling a designer that his designs could be improved is much like telling a mother that her baby is ugly!

It is important, therefore, to involve the designers in the analysis and provide them with the incentive to produce better designs. If they perform the analysis of their own designs, they are less likely to feel criticized.

Perception that a Product with Low Assembly Costs Will Not Benefit from DFMA. The first step in the application of DFMA is a DFA analysis of the product or subassembly. Quite frequently, it will be suggested that because assembly costs for a particular product form only a small proportion of the total manufacturing cost, there is no point in performing a DFA analysis. However, like the sample analysis described earlier, the savings in part costs are invariably much greater than the savings in assembly cost.

Perception that a Low-Volume Product Will Not Benefit from DFMA. The view is often expressed that DFMA is only worthwhile when the product is manufactured in large quantities. It can be argued, though, that use of DFMA is even more important when the production quantities are small. This is often because reconsideration of an initial design is not usually carried out for low-volume production. Applying the philosophy "do it right the first time" becomes even more important, therefore, when the production quantities are small.

"The Database Doesn't Apply to Our Product." Everyone seems to think that their own company is unique and, therefore, in need of unique databases rather than the ones incorporated within the DFMA software. However, when one design is rated better than another using the software databases, it would almost certainly be rated in the same way using a customized database. Remembering that there is a need to apply DFMA at the early design stage before detailed design

has taken place, there is a need for a generalized database for this purpose. Later, when more accurate estimates are desired, the user can employ a customized database if necessary.

"We've Been Doing It for Years." When this claim is made, it usually means that some procedure for "design for producibility" has been in use in the company. However, design for producibility usually means detailed design of the individual parts of an assembly for ease of manufacture. It was stated earlier that such a process should only occur at the end of the design phase. The important decisions affecting total manufacturing costs will already have been made. In fact, there is a great danger in implementing design for producibility in this way.

It has been found that the design of individual parts for ease of manufacture can mean, for example, limiting the number of bends in a sheet metal part. This invariably results in a more expensive assembly where several simple parts are fastened together, rather than a single, more complicated part. Again, experience has shown that it is important to combine as many features in one part as possible. In this way, full use is made of the abilities of the various manufacturing processes.

Confusion with Value Analysis. It is true that the objectives of DFMA and value analysis (VA) are the same (see the article "Value Analysis in Materials Selection and Design" in this Volume). However, it should be realized that DFMA is meant to be applied early in the design cycle, and that VA does not give proper attention to the structure of the product and its possible simplification. DFMA has the advantage that it is a systematic step-by-step procedure, which can be applied at all stages of design and challenges the designer or design team to justify the existence of all the parts and consider alternative designs. Value analysis, on the other hand, only looks at major parts; it is often the screws and washers--often not even shown on the drawings--that impose the difficulties during assembly.

Experience has shown that DFMA can still make significant improvements even after VA has been carried out.

Perception that DFMA is Only One among Many Techniques. Since the introduction of DFMA, many other acronyms have been proposed, for example, design for quality (DFQ), design for competitiveness (DFC), design for excellence (DFE), and now the all-inclusive design for "X" (DFX). Many have even suggested that design for performance is just as important as DFMA. One cannot argue with this. However, DFMA is the subject that has been neglected over the years while adequate consideration has always been given to the design of a product for performance, appearance, and so forth. The other factors, such as quality, reliability, and so forth, will follow when proper consideration is given to the manufacture and assembly of the product. The earlier example from Motorola (Fig. 10) illustrates how DFMA can lead to higher product quality.

Perception that DFMA Leads to Products that Are More Difficult to Service. It has been claimed that DFMA leads to products that are more difficult to service. However, experience shows that a product that is easy to assemble is usually easier to disassemble and reassemble. In fact, those products that need continuous servicing, involving the removal of inspection covers and the replacement of various items, should have DFMA applied even more rigorously during the design stage. How many times is an inspection cover originally fitted with numerous screws found with only two screws replaced after the first inspection?

"I Prefer Design Rules." There is a danger in using design rules, because they can guide the designer in the wrong direction. Generally, rules attempt to force the designer to think of simpler-shaped parts that are easier to manufacture. In an earlier example, it was pointed out that this can lead to more complicated product structures and a resulting increase in total product costs. In addition, in considering novel designs of parts that perform several functions, the designer needs to know the penalties when the rules are not followed. For these reasons, the systematic procedures embodied in DFMA software, which guide the designer to simpler product structures and provide quantitative data on the effect of any design changes or suggestions, are found to be the best approach.

General Resistance. Although a designer may not say that he refuses to use DFMA, if he does not have the incentive to adopt this philosophy and use the tools available, then no matter how useful the tools or how simple they are to apply, they will not work. Therefore, it is imperative that the designer or the design team is given the incentive and the necessary facilities to incorporate considerations of assembly and manufacture during design.

The main argument, however, against any reservations about adopting DFMA are the savings in manufacturing costs obtained by the hundreds of companies worldwide that have adopted the system, some examples of which have been described here.

Geoffrey Boothroyd, Boothroyd Dewhurst, Inc.

Design for Automatic Assembly

For many years it has been felt that automatic assembly can significantly improve productivity, and during the early days of development of DFA, there was great interest in how to design products for automatic assembly. It is clearly unlikely that a product will be designed so that it will be impossible to assemble manually. However, if a product is to be assembled automatically, then it is essential that the product be designed with the automation in mind. Otherwise, there are likely to be many parts that would be impossibly expensive to feed and orient automatically and insert automatically. It can be said that, if a product is designed for ease of automatic assembly, then it will also be easy to assemble manually.

As DFA software for automatic and manual assembly became available in 1981, most companies were happy to use design for manual assembly because it attacked the most important aspects of design for assembly, namely, the reduction in part count. In addition, very few mechanical items were assembled automatically. Some years ago it was estimated that only about 6% of all mechanical assemblies were assembled on automatic machines.

Experience has shown that in product design for ease of automatic assembly, the most important aspect is the automatic feeding and orienting of the individual parts.

It has been seen that the most obvious way to facilitate the manual assembly process at the design stage is to reduce the number of different parts to a minimum. When considering product design for automatic assembly, it is even more important to consider reduction in the number of separate parts. For example, the elimination of a part can eliminate a complete station on an assembly machine, including the parts feeder, the special workhead, and the associated portion of the transfer device.

Apart from product simplification, automatic assembly can be facilitated by the introduction of guides and chamfers that directly facilitate assembly. Sharp corners should be removed so that the part to be assembled is guided into its correct position during assembly and requires less control by the placement device.

The types of screws used in automatic assembly are important. Screws such as those with a conical or oval point that tend to centralize themselves in the hole give the best results.

A major factor to be considered in design for automatic assembly is the difficulty of assembly from directions other than directly above. The aim of the designer should be to allow for assembly in sandwich or layer fashion, with each part placed or inserted from above. One advantage of this method is that gravity is useful in the feeding and placement of parts. It is also desirable to have workheads and feeding devices above the assembly station, where they will be accessible in the event of a fault due to the feeding of a defective part. Assembly from above may also assist in the problem of keeping parts in their correct positions during the machine index period, when dynamic forces in the horizontal plane might tend to displace them. In this case, with proper product design, where the parts are self-locating, gravity should be sufficient to retain the part until it is fastened or secured.

It is necessary in automatic assembly to have a base part on which the assembly can be built. This base part must have features that make it suitable for quick and accurate location on the work carrier.

Design of Parts for Feeding and Orienting. In automatic assembly, parts obtained in bulk are placed in feeders that will separate, orient, and deliver them to the placement device. If parts are to be automatically fed and oriented, it is essential that they be designed appropriately. For example:

- Parts should not tangle, nest, or shingle.
- Ideally, parts should be symmetrical.
- If parts cannot be made symmetrical, slight asymmetry or asymmetry resulting from small or nongeometrical features should be avoided.

While the asymmetrical feature of a part might be exaggerated to facilitate orientation, an alternative approach is to deliberately add asymmetrical features for the purpose of orienting.

Clearly, with some parts it will not be possible to make design changes that will enable them to be handled automatically; for example, very small parts or complicated shapes formed from thin strips are difficult to handle in an automatic environment. In these cases, it is sometimes possible to manufacture the parts on the assembly machine or to separate them from the strip at the moment of assembly. Operations such as spring winding or blanking out thin sections can be successfully introduced on assembly machines.

Product Design for Robot Assembly. Several important product design aspects will be affected if assembly robots are to be incorporated in the assembly system. There are two basic types of robot assembly systems:

- Single-station with one or two robot arms
- Multistation transfer machine with robots, special-purpose workheads, and manual assembly station as appropriate

For a single-station system, parts that require manual handling and assembly and that must be inserted during the assembly cycle present special problems. For reasons of safety, it is usually necessary to transfer the assembly to a location or fixture outside the working environment of the robot. This can be accomplished by having the robot place the assembly on a transfer device that carries the assembly to the manual station. After the manual operation has been completed, the assembly can be returned in a similar manner to within reach of the robot. Such an arrangement is costly and time consuming.

The use of special-purpose workheads for insertion or securing operations can present similar problems. Two different situations can be encountered. In the first, the robot inserts or places the part without securing it immediately. This operation is followed by transfer of the assembly to an external workstation where the securing operation is carried out. In the second situation, a special-purpose workhead is engineered to interact with the robot at the work fixture. This might take the form of equipment activated from the sides of, or underneath, the work fixture to carry out soldering, tab bending or twisting operations, spin riveting, and so forth, while the robot has to place and, if necessary, manipulate the part.

These major problems with single-station systems do not occur with the multistation system, where manual operations or special-purpose workheads can be assigned to individual stations as necessary. This illustrates why it is important to know the type of assembly system likely to be employed when the product is being designed.

It is also necessary to know which presentation method will be used for each part. In practice, there are usually only two choices: a special-purpose feeder or a manually or automatically loaded magazine pallet or part tray. If manually loaded magazines are used, the time to hand-load the parts into the magazines must be taken into account when the choice of presentation device is made.

Design Rules for Robot Assembly. Many of the rules for product design for manual assembly and special-purpose automatic assembly also apply to product design for robot assembly. However, when the suitability of a proposed design for robot assembly is considered, the need for any special-purpose equipment such as special grippers or special feeders should be noted. The cost of this special equipment must be amortized over the total life volume of the product and, for the midrange volumes to which robot assembly might be applied, this can add considerably to the cost of assembly.

The following are some specific rules to follow during product design:

- Reduce part count; this is a major strategy for reducing assembly, manufacture, and overhead costs, irrespective of the assembly system to be used.
- Include features such as leads, lips, and chamfers to make parts self-aligning in assembly. Because of the relatively poor repeatability of many robot manipulators compared to special-purpose workhead mechanisms, this is an important measure to ensure consistent fault-free part insertions.
- Ensure that parts that are not secured immediately on insertion are self-locating in the assembly. For multistation robot assembly systems or single-station systems with one robot arm, this is an essential design rule. Holding down of unsecured parts cannot be carried out by a single robot arm, and so special

fixturing is required, which must be activated by the robot controller. This adds significantly to special-purpose tooling and, hence, assembly costs. With a two-arm single-station system, one arm can, in principle, hold down an unsecured part while the other continues the assembly and fastening processes. In practice, this requires one arm to change end-of-arm tooling to a hold-down device; the system then proceeds with 50% efficiency while one arm remains immobile.

- Design parts so that they can all be gripped and inserted using the same robot gripper. One major cause of inefficiency with robot assembly systems arises from the need for gripper or tool changes. Even with rapid gripper or tool-change systems, each change in a special gripper and then back to the standard gripper can be the equivalent of two assembly operations. Note that the use of screw fasteners results in the need for tool changes because robot wrists can seldom rotate more than one revolution.
- Design products so that they can be assembled in layer fashion from directly above (*Z*-axis assembly). This ensures that the simplest, least costly, and most reliable four-degree-of-freedom robot arms can accomplish the assembly tasks. It also simplifies the design of the special-purpose work fixture.
- Avoid the need for reorienting the partial assembly or manipulating previously assembled parts. These operations increase the robot assembly cycle time without adding value to the assembly. Moreover, if the partial assembly has to be rotated to a different resting aspect during the assembly process, this will usually result in increased work-fixture cost and the need to use a more expensive six-degree-of-freedom robot arm.
- If parts are to be presented using automatic feeders, ensure that they can be fed and oriented using simple tooling. Follow the rules for ease of automatic part feeding and orientation discussed earlier. Note, however, that feeding and orienting at high speed is seldom necessary in robot assembly and that the main concern is that the features defining part orientation can be easily detected.
- If parts are to be presented using automatic feeders, ensure that they can be delivered in an orientation from which they can be gripped and inserted without any manipulation. For example, avoid situations in which a part can be fed in only one orientation from which it must be turned over for insertion. This will require a six-degree-of-freedom robot and a special gripper or a special 180°-turn delivery track; both solutions lead to unnecessary cost increases.
- If parts are to be presented in magazines or part trays, ensure that they have a stable resting aspect from which they can be gripped and inserted without any manipulation by the robot. It should be noted that, if the production conditions are appropriate, the use of robots holds advantages over the use of special-purpose workheads and that some design rules can be relaxed. For example, a robot can be programmed to acquire parts presented in an array, such as a pallet or part tray that has been loaded manually, thus avoiding many of the problems arising with automatic feeding from bulk.

Geoffrey Boothroyd, Boothroyd Dewhurst, Inc.

Conclusions

DFMA provides a systematic procedure for analyzing proposed designs from the point of view of assembly and manufacture. It encourages teamwork and a dialogue between designers and the manufacturing engineers, and any other individuals who play a part in determining final product costs during the early stages of design.

The use of DFMA software often produces a considerable reduction in part count, resulting in simpler and more reliable products that are less expensive to assemble and manufacture.

As discussed previously, there are many widely publicized DFMA case studies to illustrate these claims. Figure 11 shows the effect of DFA on part count reduction from published case studies, and Table 7 presents details of other improvements from the same case studies.

Table 7 Various improvements due to application of DFMA software

Category	No. of cases	Average reduction, %
Part count	61	56
Assembly time	38	62
Product cost	21	50
Assembly cost	17	45
Assembly operations	14	57
Separate fasteners	12	72
Labor costs	8	42
Manufacturing cycle	6	58
Weight	6	31
Assembly tools	5	69
Part cost	3	56
Unique parts	3	57
Material cost	3	37
Manufacturing process steps	3	45
No. of suppliers	3	55
Assembly defects	3	68
Cost savings per year	6	$1,283,000

From 74 published case studies

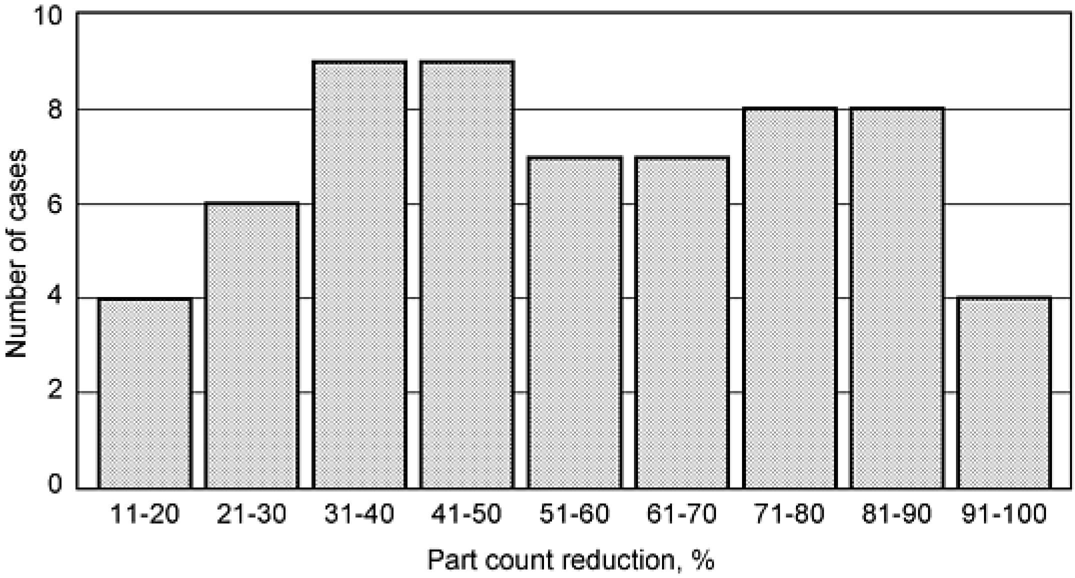

Fig. 11 Part count reductions when DFMA software was used (from 74 published case studies)

In spite of all the success stories, the major barrier to DFMA implementation continues to be human nature. People resist new ideas and unfamiliar tools or claim that they have always taken manufacturing into consideration during design. The DFMA methodology challenges the conventional product design hierarchy. It reorders the implementation sequence of other valuable manufacturing tools, such as statistical process control and Taguchi methods. Designers are traditionally under great pressure to produce results as quickly as possible and often perceive DFMA as yet another time delay. In fact, as numerous case studies have shown, the overall design development cycle is shortened through use of early manufacturing analysis tools, because designers can receive rapid feedback on the consequences of their design decisions where it counts--at the conceptual stage.

Overall, the facts are that DFMA is a subject that has been neglected over the years while adequate consideration has always been given to the design of a product for performance, appearance, and so forth. The other factors such as quality, reliability, and so forth will follow when proper consideration is given to the manufacture and assembly of the product. In

order to remain competitive in the future, every manufacturing organization will have to adopt the DFMA philosophy and apply cost quantification tools at the early stages of product design.

For a more complete treatment of the subject of this article, see Ref 27.

Manufacturing Processes and Their Selection

John A. Schey, University of Waterloo

Introduction

ENGINEERING DESIGN and manufacturing process selection are intricately interwoven; recognition of this interdependence is the basis of concurrent engineering. For this discussion, it is assumed that the functional requirements imposed on a discrete part have led to the definition of shape and properties and, together with this, to a preliminary choice of processes. This may have taken place formally, for example, with the aid of the material and process selection charts of Ashby (Ref 1) (see the articles "Overview of the Materials Selection Process," "Material Property Charts," and "Relationship between Materials Selection and Processing" in this Volume), or by the less formal approach practiced by many, in which acquaintance with production methods influences the choice. There are dangers with both approaches. The array of manufacturing processes is vast and is not easily fitted into a few charts; as pointed out by Ashby, his charts lead only to a preliminary selection. When process choice is based on the individual's knowledge, close familiarity with one process or one class of processes can lead to premature process choice and rejection of potentially valuable alternatives. Recently developed expert systems (see, for example, the article "Design for Manufacture and Assembly" in this Volume and Ref 2) facilitate process selection from a much broader perspective.

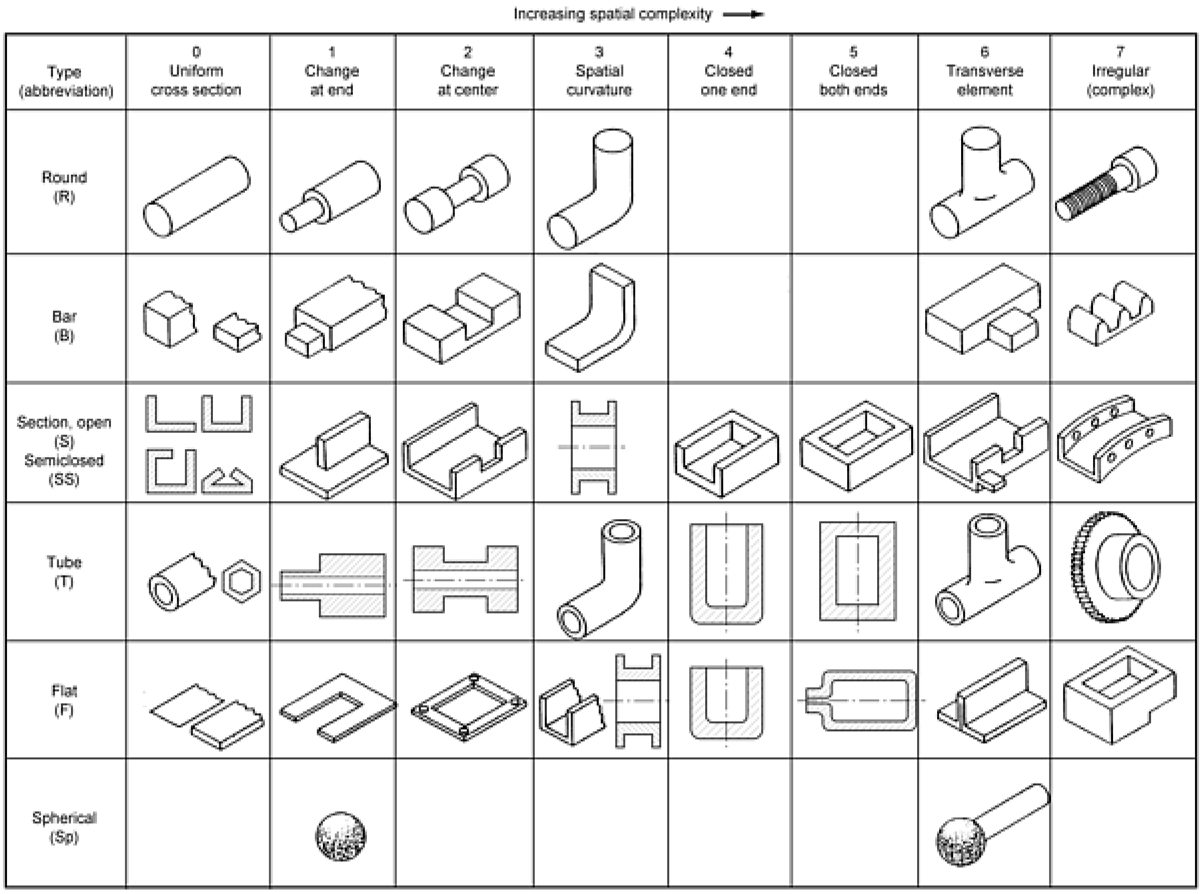

Fig. 1 The choice of possible manufacturing methods is aided by classifying shapes according to their geometric features. Source: Ref 16

The treatment adopted in this article assumes some familiarity with processes normally described in introductory books on manufacturing processes (Ref 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18). It emphasizes process characteristics that have an influence on process selection, and expands and updates textbook material (Ref 16). Once technical feasibility is established, process choice is further narrowed by cost and availability. In the case of a "buy" decision, cost is readily determined by comparing quotes from vendors. True costs of in-house production are often difficult to establish unless a well-designed accounting system is in place. In either case, costs associated with further processing of parts must form an integral part of informed decision making.

Detailed design rules for specific processes are given in later articles in this Section; this article explores the possibilities and limitations imposed by the process and material. Process groups are discussed in the sequence followed in the rest of this Section. For ease of discussion, main features of process groups are presented in tabular form. The tables are meant to give general guidelines only and are based on good standard practices. Inventive approaches often allow production to much higher quality, broader size range, lower cost, and so forth. Each table contains physical characteristics and ratings of relative cost and production factors. Examples of typical products given in the text are meant to be only illustrative and in no way limiting.

Manufacturing Processes and Their Selection

John A. Schey, University of Waterloo

Product Considerations

Some factors have an influence in all processes and need to be discussed further. The factors include size, shape complexity, tolerances and surface finish, and production volume.

Size. There are limits to size in both extremes. The minimum size is often dictated by physical constraints. For example, surface tension and freezing of a metal melt limit the smallest size of a mold cavity that can be filled. The minimum can be reduced but not eliminated by filling under pressure; the minimum is different for different alloys. Radically different techniques, mostly based on methods used for making semiconductor devices, push the limit much lower (nanotechnology). The maximum is more often set by the largest size of equipment available, although there may also be physical limitations. For example, the size of hot impression-die forgings or injection-molded plastic parts is limited by the largest press available, while the thickness of a plastic part is limited by loss of shape due to shrinkage.

Shape Complexity. Shape is an essential feature of all manufactured parts; complexity of this shape often determines what processes can be considered for making it. In the most general sense, increasing complexity narrows the range of processes and increases cost. A cardinal rule of design is, therefore, to keep the shape as simple as possible. This rule may, however, be broken if a more complex shape allows consolidation of several parts and/or elimination of one or more manufacturing steps.

There is no universally accepted shape classification system. The groupings given in Fig. 1 are used in the tables that list process attributes. Products of uniform cross section (spatial complexity = 0) are two-dimensional, all others are three-dimensional. With increasing spatial complexity, definition of the shape requires additional geometric parameters; in the terminology of Ashby (Ref 1), the shape has greater information content. A small increment in information content can, however, have significant manufacturing consequences. For example, moving from the solid shape R1 to the hollow shape T1 adds only one dimension (the diameter of the hole, with appropriate tolerances and specifications for concentricity), yet it immediately excludes some processes or necessitates extra operations in others. Adding a third diameter to the round product R1 would result in the same increase in information content yet does not impose limitations of process choice. One of the aims of group technology is classification of shapes suitable for processing by the same techniques (see the article "Introduction to Manufacturing and Design" in this Volume).

Limitations on shape are tightened by properties of the material and by interactions with the tooling. Wall or section thickness are affected, as shown in Fig. 2, and discussed further in conjunction with process groups. The aim is, generally, to produce a "net-shape" part ready for assembly; if this is not feasible, a "near-net-shape" part will need only minor finishing, usually by machining.

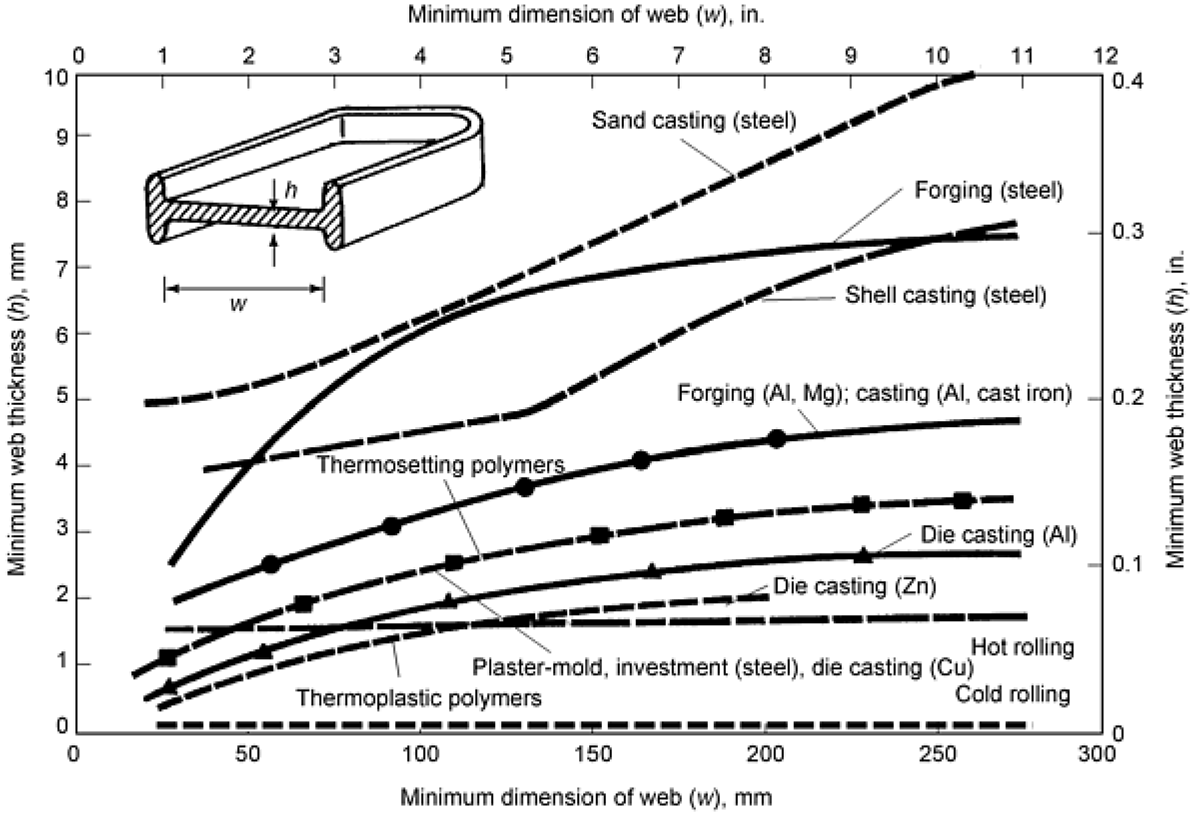

Fig. 2 For a given process, the minimum web thickness increases with the distance over which material must move. Source: Ref 16

Tolerances and Surface Finish. The article "Overview of the Materials Selection Process" in this Volume gives a general discussion of these aspects; the concern in this article is their manufacturing implication.

Tolerances. No manufacturing process can deliver a perfect geometrical shape. The permissible deviations are expressed by tolerances (see the article "Dimensional Management and Tolerance Analysis" in this Volume), and some processes are inherently more suitable for delivering parts to close tolerances (see Fig. 5 in the article "Overview of the Materials Selection Process" in this Volume).

Surface Topography. In addition to deviations from the ideal shape, the surface of manufactured parts is never perfectly smooth. Roughness is not necessarily undesirable. Sheet used for making an automobile body panel must have controlled, random roughness features to facilitate pressing and give desirable surface appearance after painting. A shaft of a journal bearing must have controlled circumferential roughness features to retain lubricant and prevent seizure. As shown by these examples, not only the degree of roughness but also the orientation (lay) of surface features relative to the direction of sliding motion are critical.

Measurement and characterization of surface topography is a rapidly developing field, and only the most commonly used approaches are discussed here. The profile of the surface (roughness and waviness) is measured by drawing a fine-pointed stylus across the surface (other, noncontacting measuring methods are available [Ref 19] and are gaining in popularity). For ease of visualization, recordings are made with greater magnification on the vertical (height) axis (Fig. 3). This makes peaks (asperities) appear much steeper than the 5 to 20° slope they really have. A centerline is computed so that the area filled with material equals the unfilled area. The average height deviation from this line is the centerline average (CLA) or arithmetic average (AA; R_a). The root-mean-square (RMS) value (R_q) is slightly smaller. When roughness-height distribution is not regular--for example, when local peaks would penetrate a lubricant film or when the surface is to be

polished--the maximum roughness height (R_t) or average height difference between 5 highest peaks and 5 deepest valleys (R_{tm}) is more informative. Because R_t/R_a is typically between 7 and 14, roughness affects the closest tolerance that can be meaningfully specified.

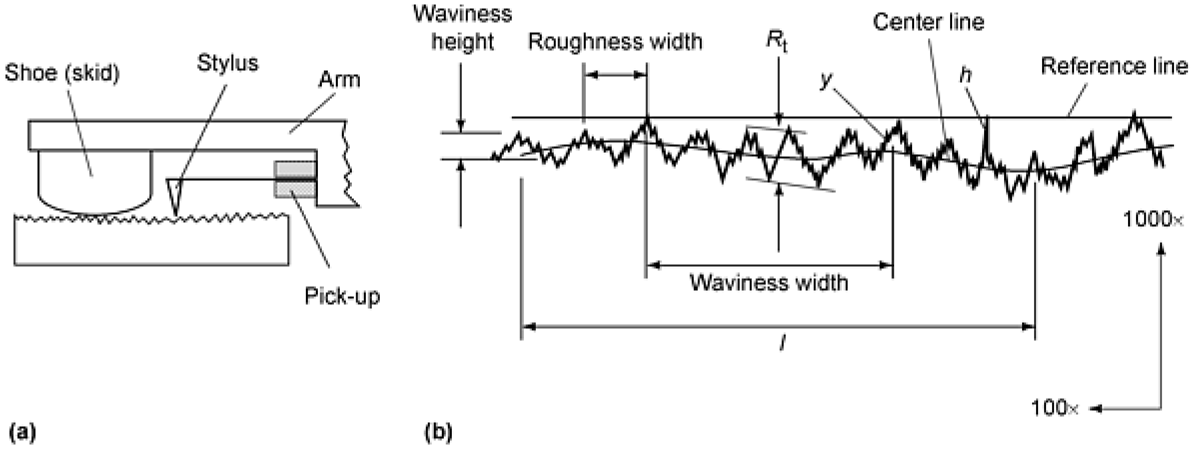

Fig. 3 Measurement (a) and characterization (b) of surface roughness. R_t, maximum roughness height; *l*, length; *y*, height from center line; *h*, distance of surface from reference surface. Source: Ref 20

Surfaces of the same R_a roughness may have very different asperity shapes (Fig. 4). Roughness height distribution is described by the Abbott curve (a plot of load-bearing areas produced by cuts taken at various levels from the top of the profile) and by the numerical values of skewness (R_{sq}) and kurtosis (R_k) (Ref 21). They affect the functional behavior of the surface. For example, automobile body sheet of positive skewness (peaky profile) is prone to form die pickup and suffer scoring.

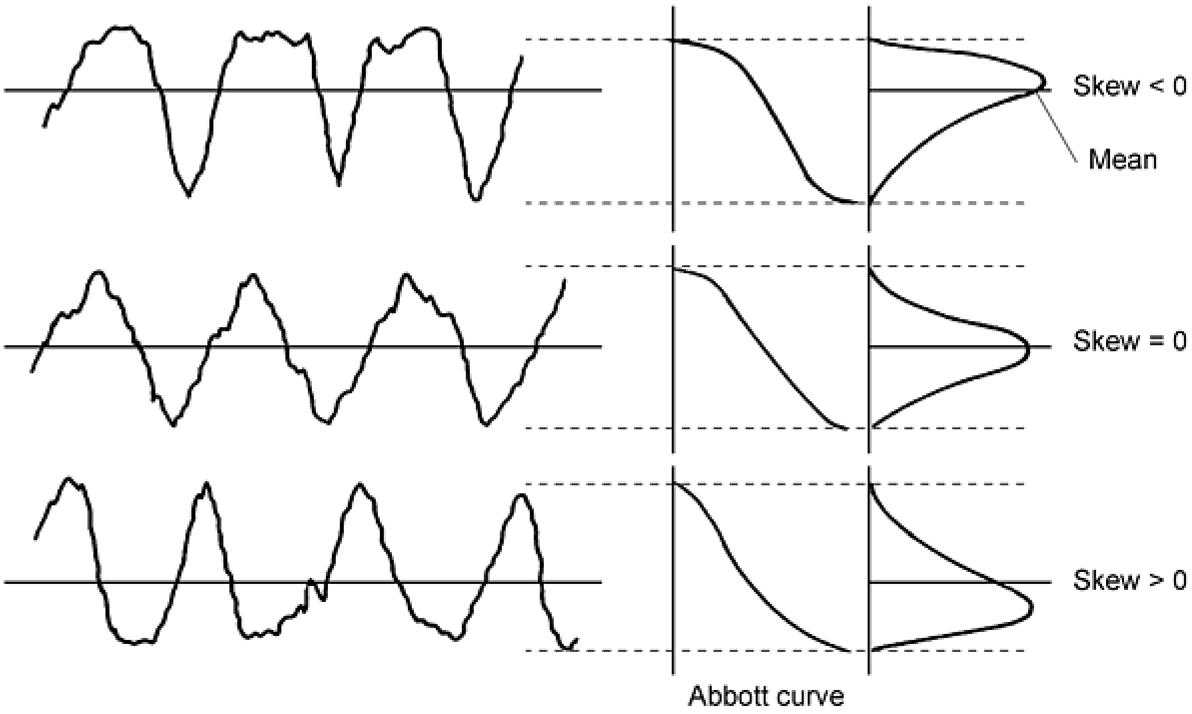

Fig. 4 Surface profiles, bearing area, and symmetry about mean for surfaces of similar average roughness. Source: after Ref 21

Production Volume. Process choice is heavily influenced by the total number of parts to be made and by the required rate of production (i.e., the number of parts produced in a given time period). In general, a larger production quantity justifies greater investment in dies, equipment, and automation, whereas small quantities are often made with more labor input.

The total number of parts is frequently produced in lots. Lot size used to be determined to a large extent by total quantity, with lot size chosen to provide a supply for several days or weeks. Some standard components such as fasteners are still produced in large lots by hard automation. However, the spread of just-in-time delivery schedules and the increasing use of quick die-changing techniques and flexible automation have contributed to shrinking lot sizes even in mass production; the limit is reached when a single part constitutes a lot.

It is not feasible to state hard rules of what the economical production quantity and lot size is. Much depends on the equipment, degree of automation, and process control available in a given plant. Relative values shown in the tables are meant to serve only as initial guidelines and are heavily influenced by the cost of dies.

Casting Processes

In all casting processes (Table 1), a metal or alloy is melted (and possibly treated while molten), poured into a mold, allowed to solidify, and the part thus produced is released from the mold. Very broadly, casting processes fall into two groups (Fig. 5): expendable-mold and permanent-mold processes. Choice of process and mold material is greatly influenced by the melting point of the alloy. A vital issue is avoidance of voids (due to insufficient feeding of melt) and porosity (due to dendritic solidification and the presence of gases). Success depends, to a large extent, on the skill of the mold designer in choosing the position and size of sprue, runners, and risers, but there are very strong influences of the metal (alloy) and mold material. Expert systems and computer modeling of die filling and solidification are increasingly employed. Even with the best design, solidification on the mold walls closes passage of melt at a certain distance, and this leads to a minimum allowable section thickness. Because with proper design of runners a part can almost always be fed across the shorter dimension, minimum web thickness increases with the width of the web (Fig. 2). There are large differences in the fluidity of alloys; therefore lower minimum thickness can be allowed with zinc, aluminum, and cast iron than with steel. Streamlined flow is helpful; thus sharp corners are avoided. Thicker sections solidify last and must be fed adequately.

Table 1 General characteristics of casting processes

Characteristic	Casting process

(a) Comparative ratings, with A indicating the highest value of the variable, E the lowest (e.g., investment casting gives very low porosity, produces excellent surface detail, involves moderate to low equipment cost, medium to high pattern cost, high labor cost, medium to low finishing cost, and high operator skill. It can be used for low or high production rates and requires a minimum quantity of 10 to 1000 to justify the cost of the pattern mold).

(b) From Fig. 1.

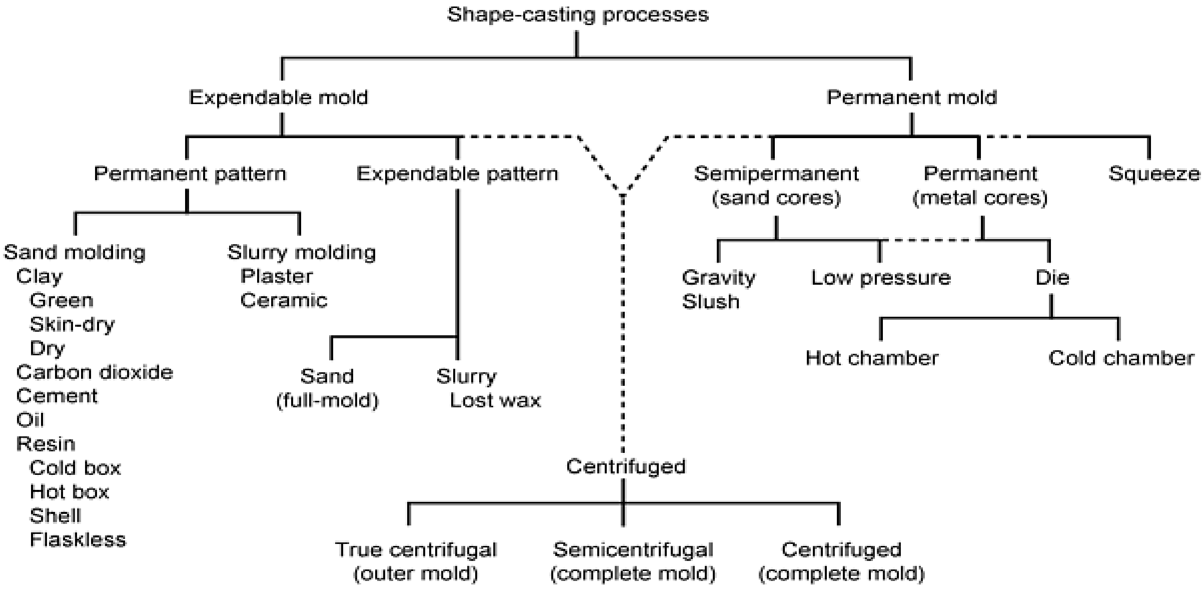

Fig. 5 General classification of shape-casting processes. Source: Ref 16

Expendable-Mold Processes

In expendable-mold casting processes, the mold is used only once and is destroyed to release the part; hence great complexity of shape is feasible. Expendable-mold processes are further divided into those using permanent patterns and those using expendable patterns.

Sand casting is used as a generic term for all processes in which an expendable mold is formed of a granular ceramic (ranging from natural sand to synthetic ceramics) by consolidation around a permanent pattern (wood, metal, or plastic), which is removed prior to filling the mold cavity with metal, necessitating the use of draft for the release of the pattern. The "sand" is bonded temporarily by clay (green clay or dry sand mold), sodium silicate (carbon dioxide, or CO_2, process), cement, or vacuum. In principle, all metals can be cast by these techniques provided the sand is refractory enough. Because cores are also destroyed upon completion of solidification, great shape complexity is possible. As a broad rule, a mold made with firmer bond allows the use of finer sand, the production of smaller parts with thinner walls, smaller cores, and greater surface detail. The low thermal conductivity of sands favors complete filling.

Costs can vary greatly. A great advantage of sand casting is that investment can be kept to a minimum with the use of wood patterns and hand molding, thus allowing even prototyping of one or a few parts, albeit at the expense of higher labor costs and greater skill. At the other end of scale, mass production with reduced labor cost and skill is possible with a substantial investment in sand preparation, distribution, mechanized molding, and sand reclamation. The ratings in Table 1 reflect these variables; the lowest-cost equipment and pattern will generally go with highest labor cost, skill requirement, and lowest productivity. The range of products is very broad, from small engine blocks to large machine-tool bases.

Resin-Bonded Sand Casting. The sand is bonded by a thermosetting polymer (resin). When the mold is a relatively thin shell, formed around a heated metal pattern, the process is referred to as shell casting. Pattern costs may be higher, but surface finish is better and tolerances are tighter.

Plaster Casting. In Table 1, this term stands for processes in which a fine-grained refractory is poured as a slurry over the pattern and is then allowed to set (plaster molding for nonferrous alloys) or is fired (ceramic-mold casting for higher-melting alloys). With proper control of refractory and shrinkages, complex parts can be cast with thin walls, close tolerances, and good surface finish, but at a higher cost.

Expendable-Pattern Casting. Patterns are melted out prior to casting in the ancient yet thoroughly modern lost-wax process for ceramic molds, or they burn up and evaporate during pouring, as does polystyrene foam in the lost-foam process for sand molds. Thus, the mold can be in one piece, eliminating parting lines. Draft is reduced to that required for releasing the pattern from its mold. Preheating of ceramic molds allows thin walls and small cores, as in superalloy turbine blades with internal cooling passages. By assembling several pattern pieces, shape complexity can reach the highest level of any manufacturing process, as exemplified by bronze castings of statues.

Permanent-Mold Processes

In permanent-mold casting processes, the mold (die) is made of a metal, and the shape is limited to geometries that can be released from two or more mold sections. Internal cavities and holes can be formed with retractable cores, as in casting aluminum-alloy pistons, but at the expense of higher cost and greater complexity of machinery. Even greater complexity is achievable when expendable cores are inserted. In all permanent-mold casting, porosity can be a problem with alloys of dendritic solidification pattern.

The metal mold can be fed by gravity (permanent-mold or gravity die casting) or under pressure (low- and high-pressure die casting). The latter ensures filling of thinner sections, especially with lower-melting alloys (Fig. 2). Highly complex shapes, such as office-machine housings and transmission cases are cast to close tolerances. The use of higher-melting alloys is limited by rapid wear of the die. Direct transfer of the melt (hot-chamber die casting) is also limited to lower-melting alloys (aluminum as the maximum) yet allows reducing or eliminating sprue and feeders. Porosity and voids are reduced or eliminated if high pressure is applied just prior to final solidification, or if the alloy is formed at a temperature between the liquidus and solidus. Such mushy-state forming (variously known as squeeze casting, melt forging, or semisolid metalworking) represents a transition between casting and hot forging processes.

It should be noted that when "All" is given for shape complexity in Table 1, the closed shape T5 can be cast only if the core is left in the casting, unless the part is made from a premeasured amount of melt that is swirled around the closed mold (slush casting, used also for complex shapes such as in casting small sculptures).

Design considerations are given in the article "Design for Casting" in this Volume.

Manufacturing Processes and Their Selection

John A. Schey, University of Waterloo

Deformation Processes

All plastic deformation processes exploit the ability of metals and alloys to change shape by plastic flow. The ability to deform without fracture is highly variable. Bulk deformation processes (Table 2) impose material flow in all directions, and the ability to deform is expressed as workability; in sheet metalworking processes deformation is essentially two-dimensional, and limits of deformation are referred to as formability. Both are discussed in the article "Relationship between Materials Selection and Processing" in this Volume. As indicated there, it is important to recognize that the limits of plastic deformation are the outputs of a system and these are greatly affected by the stress state prevailing in the process. If stresses are highly compressive (in other words, if a hydrostatic pressure component prevails), even a material of low workability can be deformed to a significant extent. Thus, process selection is based on a knowledge of the workability or formability of the material and its variation with stress state, strain rate, and temperature. Because most processes involve sliding contact between the workpiece and a tool or die, friction affects material flow, die pressures, and force and energy requirements. In most instances lubricants are chosen to minimize friction, but in some cases control of (and not necessarily low) friction is the aim. Lubricants also fulfill the important functions of reducing die wear, cooling (or temperature control), and control of the surface topography of the product (Ref 19).

Bulk Deformation Processes

The starting material in bulk deformation processes is a slab, ingot, billet, and so forth, produced by casting into stationary molds or by continuous casting techniques (Fig. 6). Primary deformation processes such as hot rolling, tube piercing, extrusion, open-die forging are then used for converting the cast structure. The product may be suitable for immediate application, but in many cases it serves as the starting material for another deformation process, the so-called secondary deformation processes, such as drawing, hot and cold forging (Fig. 6), and sheet metalworking (Fig. 7).

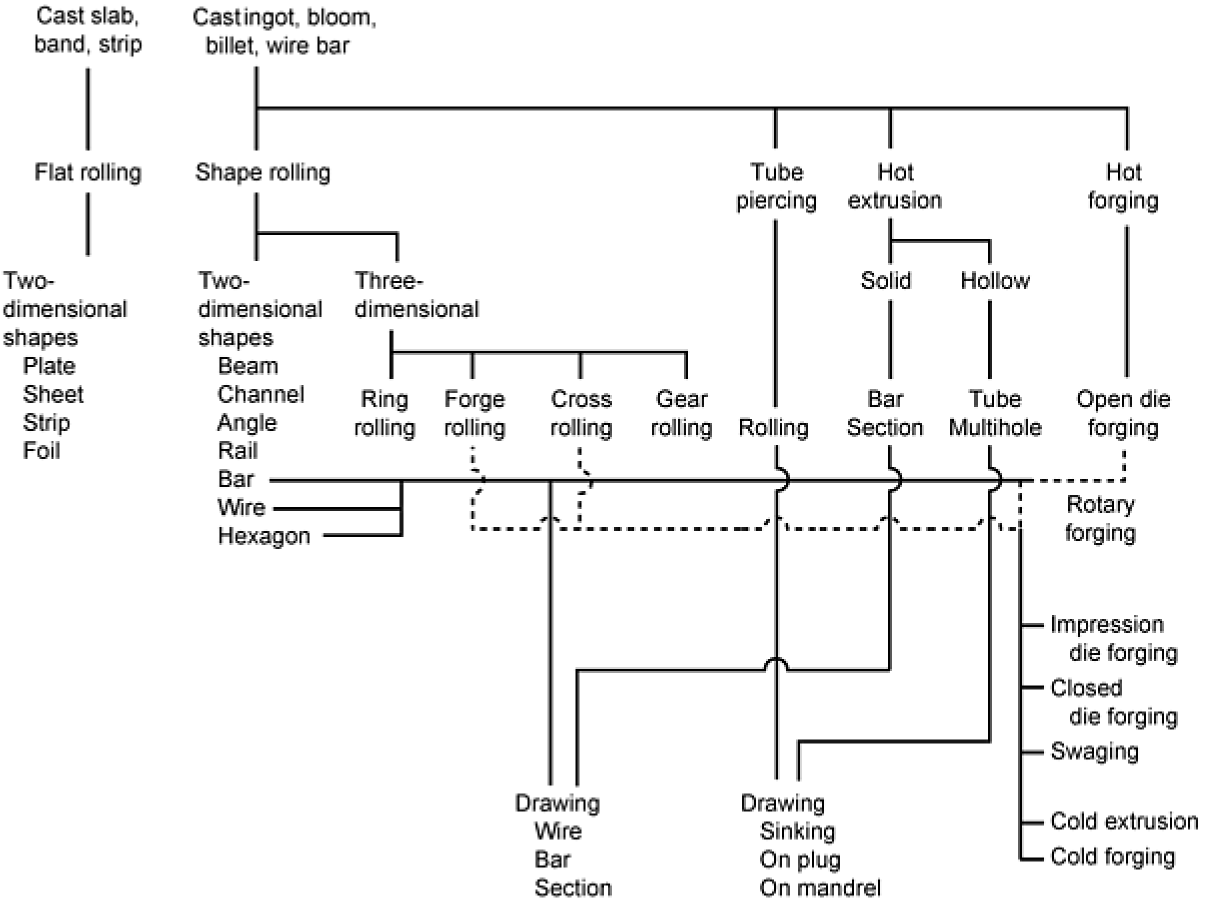

Fig. 6 General classification of bulk deformation processes

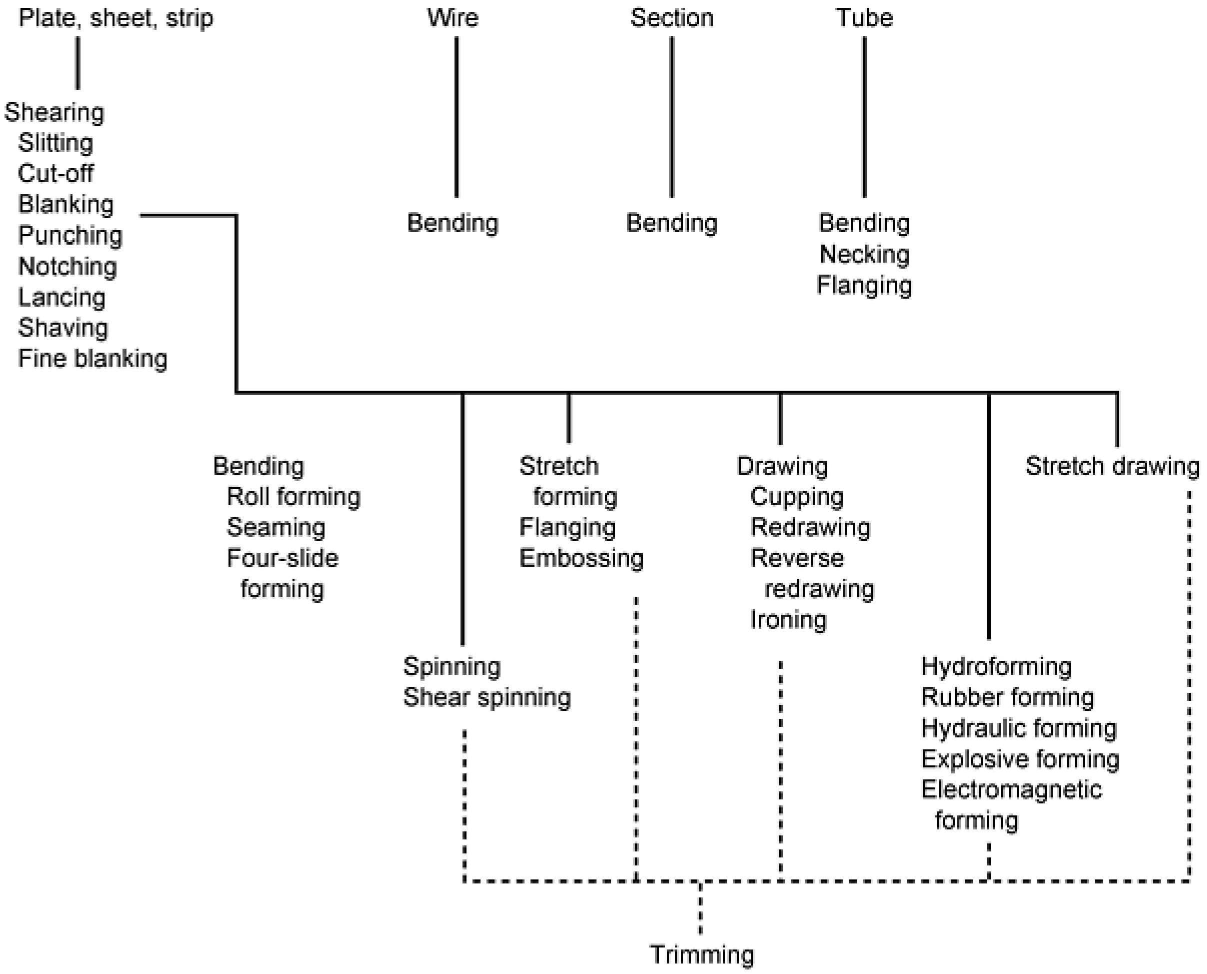

Fig. 7 General classification of sheet metalworking processes

Much primary working is conducted at elevated temperature, in the hot-working temperature range (typically above one-half the melting point on the absolute temperature scale) where dynamic recovery and recrystallization ensure low flow stress and high workability. Because recovery processes take time, flow stress σ_f is a function of strain rate $\dot{\varepsilon}$:

$$\sigma_f = C\,\dot{\varepsilon}^m \qquad \textbf{(Eq 1)}$$

where C is the strength coefficient (decreasing with increasing temperature) and m is the strain-rate sensitivity exponent. A high m value means that an incipient neck becomes stronger and spreads to neighboring material, allowing more deformation in tension. This is important also for glasses and polymers, in which m can reach unity (Newtonian flow). In some very fine-grained metals the value of m may reach 0.4 or 0.5, but only at very low strain rates and in a limited temperature range, and then superplastic deformation is possible to large strains and with low stresses.

Cold working produces better surface finish, can impart higher strength, and allows thinner products, but at the expense of higher forces. Flow stress is now primarily a function of true strain ε:

$$\sigma_f = K\,\varepsilon^n \qquad \textbf{(Eq 2)}$$

where K is the strength coefficient and n is the strain-hardening exponent. A high n-value allows more tensile deformation before localization of a neck. The value of K increases and n decreases in the course of cold working; thus ductility is reduced and forces increase. Intermediate (process) anneals can restore ductility and reduce forces, but at an additional cost. Warm working in an intermediate temperature range can combine some of the benefits of hot and cold working. Many processes are capable of producing net-shape or near-net-shape products, and Table 2 refers to these. Limits of size

and web thickness are often set by the pressure increase due to friction at high width-to-thickness ratios (Fig. 2). Design rules for components are given in the article "Design for Deformation Processes" in this Volume.

Rolling is the most important primary working process, practiced in highly specialized, high-productivity, capital-intensive plants. The products of flat hot rolling are relatively thick plate, sheet, and strip, typically down to 1.6 mm (0.060 in.). Cold rolling is capable of producing the thinnest of all metal products (strip and foil, to a few micrometers or a fraction of a thousandth of an inch) to very tight tolerances and controlled surface finish. Most of these products are further processed in sheet metalworking operations (Fig. 7). Hot-rolled bar and wire serve as starting materials for other bulk deformation processes or machining. Shapes are mostly hot rolled or hot extruded for structural applications, although cold-rolled precision shapes fill an important niche. All these processes yield products of two-dimensional configuration, in often very long lengths, and are capable of producing high-quality (close-tolerance) products at very high rates and low cost. Closer to final application are three-dimensional products of hot and cold ring rolling (rotating rings of jet engines, ball-bearing races), forge rolling for complex shapes (cutlery), gear rolling, and cross (transverse) rolling for shapes of axial symmetry (preforms for forging double-ended wrenches). Seamless tubes are made by hot piercing or hot extrusion and are further reduced by special rolling processes for immediate use (for example, in oil fields) and for further working, including cold reduction and drawing.

Drawing. A rolled preform is drawn through a converging gap, usually cold. Round bars and wires as well as two-dimensional sections of often complex cross-sectional shape are drawn through stationary dies or, less frequently, rollers. Tubes may be simply drawn through a die (tube sinking), but more often wall thickness reduction is achieved by drawing over a plug or a bar (also called mandrel, from which the tube is released by cross rolling). Die costs are relatively low and production rates can be high, making for low-cost, high-precision products of wide size and wall-thickness range.

Extrusion. A billet held in a container is pushed against a die (direct or forward extrusion), or the die penetrates the billet (indirect or reverse extrusion), either hot or cold. Friction over the container and die surfaces has a decisive influence on material flow and die pressures.

Only lower-melting alloys, including aluminum alloys, can be extruded hot without a lubricant, and then deformation occurs with shearing the alloy at the die-to-billet interface. Two-dimensional shapes of great complexity and thin walls (e.g., architectural extrusions) can be made at a relatively low die cost. In the absence of a lubricant, divided material strains can be reunited and welded in a bridge-type die, allowing extrusions with one or more closed cavities, in a very wide size range (multihole tubes are extruded with walls as thin as 0.25 mm, or 0.010 in.). Hot extrusion of higher-melting alloys requires a high-temperature lubricant, often a glass; shapes are more limited and wall thickness is greater. The purpose may be that of producing a two-dimensional semimanufactured product or, if part of the billet is retained at the starting diameter, that of making near-net-shape three-dimensional products such as large valves and fasteners. The skill of the die designer is called upon to ensure a sound product.

Cold extrusion is always conducted with an effective lubricant (often with the lubricant superimposed on or reacted with a conversion coating on the metal) and is normally used to create near-net-shape products such as fasteners, automotive components, and so forth. Impact extrusion is a term employed for the cold extrusion of thin-walled products such as toothpaste tubes.

Forging. The aim in most forging operations is that of producing a part as close to the finished shape as possible.

Open-die forging uses simple tools in a programmed sequence of basic operations (upsetting, drawing out), mostly in the hot-working temperature range, and the products (ranging from the one-off products of the blacksmith to huge turbine rotors) usually require finishing by machining. Rotary forging and swaging on special-purpose machines produce parts of axial symmetry to much tighter tolerances (axles, gun barrels).

Hot impression-die forging (sometimes termed closed-die forging) shapes the part between two die halves; thus productivity is increased, albeit at the expense of higher die costs. Excess metal is allowed to escape in the flash; thus pressure is kept within safe limits while die filling is ensured. More complex shapes, thinner walls, and thinner webs may necessitate forging in a sequence of die cavities, as for connecting rods and crankshafts. Die design calls for a thorough knowledge of material flow and is greatly aided by computer models and expert systems. At high width-to-thickness ratios friction sets a limit to minimum web thickness (Fig. 2) that decreases with effective lubrication. In true closed-die forging the material is trapped in the die cavity.

With dies heated to or close to forging temperature (isothermal or hot-die forging), cooling is prevented and thin walls and webs can be produced, provided the die material is stronger than the workpiece material at the temperatures and strain rates prevailing in the process. This is relatively easy for aluminum alloys (airframe parts); low press speeds (low $\dot{\varepsilon}$) help to keep stresses and forces low. Titanium alloys and superalloys can be forged in the superplastic state (jet-engine fan blades and turbine disks).

The sequence of operations can be carried out by moving the heated end of a bar through the die cavities in an upsetter, achieving high production rates. Mechanized transfer between cavities in conventional presses is also possible. In all impression-die forging, die design calls for considerable knowledge and die cost can be high (Table 2), but the product often has superior properties because material flow can be directed to give the best orientation of the structure relative to loading direction in the service of the part.

Cold forging is related to cold extrusion and, when a complex shape is to be formed in a single step, requires special lubricants, often with a conversion coating, as in making spark-plug bodies. Alternatively, the shape is developed by moving the bar or slug through a sequence of cavities, using a liquid lubricant. Cold forging is often combined with cold extrusion. It is the preferred process for mass producing near-net-shape parts such as bolts, nuts, rivets, and many automotive and appliance components.

Sheet Metalworking Processes

The starting material is a flat-rolled product (hot-rolled plate, hot- or cold-rolled sheet or strip); hence there are no limitations on width-to-thickness ratios: sheet metalworking is the process of choice for relatively thin products. Deformation is mostly by tension or tension-compression, and limits are set by the formability of the material (see the article "Relationship between Materials Selection and Processing" in this Volume) and only rarely by force or die pressure. Most processes are conducted cold; only heavy-gage material is formed hot. Major process groups are shown in Fig. 7, and characteristics of major processes are given in Table 3. Forming of wires, sections, and tubes is governed by the same rules as the forming of sheet; therefore, it is included here.

Table 3 General characteristics of sheet metalworking processes including bar and tube bending

(a) From Fig. 1.

(b) Comparative ratings, with A indicating the highest value, E the lowest (see example in Table 1).

Shearing. The purpose of shearing is controlled separation to: slit narrower strips, separate parts (cut-off, parting), cut out a part (blanking), create a hole (punching), produce notches, and so forth. The basic shearing process relies on cracks penetrating from both sides of the sheet. With proper clearance between punch and die, the cracks meet but the cut surface is slightly inclined and rough. Tool wear results in the formation of a ragged burr that causes stress concentrations and may lead to fracture during further forming or in service. In fine blanking, crack formation is suppressed by the hydrostatic pressure generated by impingement rings, and a smooth, perpendicular surface, suitable as the contact surface on a net-shape part, is produced, but at higher die and equipment cost.

Bending. In addition to sheets (or blanks), sections, tubes, and wires are bent to a great variety of shapes. Accuracy is improved with proper control of or compensation for springback. Limits are imposed by local necking, fracture, or--for aesthetic reasons--by orange-peel formation. Four-slide machines are capable of performing several operations on three-dimensional parts at high production rates. Roll forming allows the mass production of two-dimensional corrugated sheet, architectural sections, and lock-seam and welded tubes. With proper design, close tolerances can be achieved. Such products are in competition with extruded, shape-rolled, and cold-drawn products. Plates and sections are often bent in three-roll benders into complete circles. Tube bending presents the challenge of preventing collapse of the tube wall; complex shapes are now bent under computer control.

Bending a sheet along a curved line is termed flanging. Circular or other close-shaped flanges (collars) are mass produced in preparation for joining tubes and fasteners to sheet, as in heat exchangers. Limits are set by fracture in a stretch flange and by buckling in a shrink flange. Related processes are flanging and necking of tubes and cans, as on beverage cans.

Stretch Forming. The blank is firmly clamped at much or all of its circumference, and the shape is developed by the penetration of a punch, at the expense of thickness. Limits are set by necking or fracture, as given by the tension-tension side of the forming limit diagram (see Fig. 6 in the article "Relationship between Materials Selection and Processing" in this Volume). Small quantities can be produced with only a punch, although at higher material cost, as in the aircraft industry. Mating dies with carefully designed blankholders are more economical for the large quantities typical of the automotive and appliance industries. An important aspect is control of or compensation for elastic recovery (springback), which distorts the shape. Embossing is a highly localized form of stretch forming.

Drawing. In contrast to stretch forming, the shape is developed by drawing material into the die, and average thickness is approximately preserved. The flange is in circumferential compression and forms wrinkles, unless the blank is thick relative to the blank diameter or is adequately restrained with a blankholder (although in some applications, such as aluminum dinner trays, wrinkling has been exploited to increase stiffness of the part). Fracture occurs at the base or in the wall if stresses exceed the strength of the partly formed cup; therefore a limit is set to the attainable reduction in diameter or, as more frequently expressed, a limiting draw ratio (LDR = diameter of blank/diameter of cup) is reached. The LDR is a system property, affected by material (especially *r*-value; see the article "Relationship between Materials Selection and Processing" in this Volume), die design, lubricant, and so forth. Cups deeper than allowed by the LDR are produced by redrawing or reverse redrawing (food cans) or by thinning the wall in ironing (beverage cans, cartridge cases).

Stretch Drawing. Parts of nonaxial symmetry are mostly produced by a combination of stretching and drawing. The relative contribution of each is controlled by blank design, blankholder pressure, or the insertion of drawbeads into the blankholder surface. Strain distribution can be analyzed by imprinting a grid on the blank surface, and remedies for necking or fracture can be found with reference to the forming limit diagram of the material. Many deeper, complex-shape sheet metal parts of automobiles are made by these techniques. Great advances are being made in die design aided by computer modeling of material flow. Hydraulic forming allows stretching or drawing with only a punch or a die; the other die element is replaced by a fluid restrained by a diaphragm, reducing die costs. Rubber forming does the same, but with an elastomeric cushion.

Special processes are those that do not fit conveniently into the above categories, but are subject to similar limitations imposed by material properties.

Spinning can produce complex axially symmetrical shapes with programmed tool movement and a relatively simple inner die (form). Wall thickness can also be reduced (shear spinning) within the workability limits of the material (see Fig. 5 in the article "Relationship between Materials Selection and Processing" in this Volume).

Special Forming Processes. Explosive forming is used for bulging or reducing tubes and for forming shapes similar to those produced by stretching. Electromagnetic forming has similar applications, primarily to tubular parts. Hydroforming of tubes utilizes internal pressure to expand the tube; axial compression feeds material into the deformation

zone and prevents excessive thinning. Originally used for making copper T-fittings, hydroforming is now growing into a mass production process for automotive components such as engine mounts.

Replacing one of the mating dies with a rubber cushion (rubber forming) or fluid contained by a rubber diaphragm (hydroforming) reduces die costs, but usually at the expense of greater material consumption. Greater depth and more complex shapes can often be obtained than with hard tooling.

Design guidelines are given in the article "Design for Deformation Processes" in this Volume.

Powder Processing

Discussion here is restricted to metal powders (powder metallurgy, P/M); ceramic powders are dealt with later in this article. Powders of metals and alloys are processed for several reasons. Most importantly, parts of complex shape, close tolerances, controlled density, and controlled (and often unusual) properties can be produced.

Powder processing involves a sequence of operations (Fig. 8). The powder is produced by various techniques: reduction of an oxide, thermal decomposition, electrolysis, hydrometallurgy, or breaking up (atomizing) a melt. Particle size is controlled during powder production or by comminution; size fractions are separated by sizing. After cleaning (and possibly annealing), alloying elements and lubricants are added by blending. There are several process routes to arrive at finished parts.

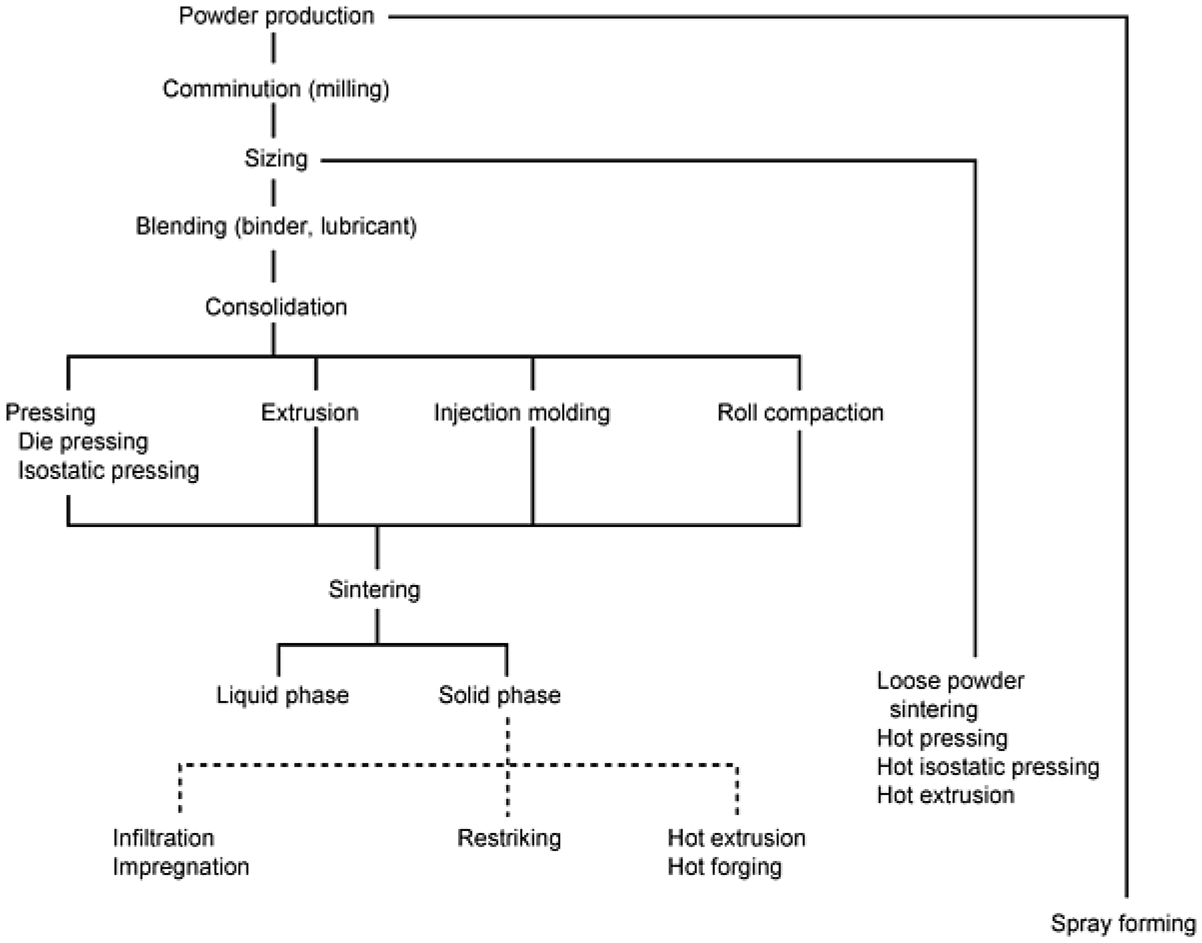

Fig. 8 General classification of powder metallurgy processes

Most parts are produced by mixing the powder with a lubricant and pressing in a die (rigid tool). Friction between particles and on the die wall results in a gradual drop in density away from the punch face. Dies with several moving elements can become very complex, but allow manufacture of parts of greatly varying web thicknesses. The "green" compact has relatively low density and very low strength. Isostatic pressing in a deformable jacket gives better density distribution for complex shapes. Roll compaction is advantageous for strip and simple two-dimensional shapes. Sintering at hot-working temperatures increases density and strength by establishing a metallurgical bond, although some porosity remains and mechanical properties are below that of parts produced by deformation processes.

Shrinkage is considerable and must be taken into account in design. Properties are, nevertheless, adequate for many applications, such as lightly loaded gears. Hot restriking closes pores and improves properties. Hot forging with substantial deformation of green or sintered preforms produces near-net-shape parts of full density, free of segregation, and of often superior properties, such as steel connecting rods and superalloy jet engine disks. Hot rolling and extrusion are practiced for making P/M tool steels of very fine grain size and carbide distribution.

Adding a polymeric binder to very fine (around 10 μm) powder allows injection molding at low pressure. Upon heating, the binder is removed (debinding) and sintering establishes the metallurgical bond. Small parts of thin walls and complex shape (even with cross-cored holes) can be produced at high density, but the high shrinkage must be taken into account in design.

Consolidation and sintering take place simultaneously during hot pressing in dies, hot isostatic pressing (HIP) in deformable jackets, and hot extrusion. Loose powder may be sintered into simple forms, as for filters. The most direct route is spray deposition of atomized powder, for sheet or finished part.

All P/M processes call for considerable knowledge and require substantial investment in equipment. Die costs increase with shape complexity and, when in competition with other processes, P/M usually becomes economical only at higher

production volumes. Powder metallurgy is irreplaceable, however, when parts with unique properties are to be made for the following reasons:

- Porosity is intentionally kept high and interconnected for metal filters
- Composite structures are formed by infiltrating a porous compact with a different metal (e.g., the impact strength of steel parts is increased by infiltrating copper; self-lubricating bearings, welding electrodes, and electrical contacts are made by infiltrating a skeleton with a different metal)
- Impregnation with oil provides reservoirs of lubricant.

Carbide powders are cemented with 3 to 15% metal such as cobalt by liquid-phase sintering for hard, temperature-resistant tooling. Powder metallurgy is often the most favorable or feasible processing route for refractory metals and alloys.

Design guidelines are given in the article "Design for Powder Metallurgy" in this Volume.

Manufacturing Processes and Their Selection

John A. Schey, University of Waterloo

Machining Processes

Parts produced by casting, deformation, and powder processing techniques frequently require some metal removal to create the final shape, meet tolerances, or obtain the requisite surface finish. Machining (Table 4) may also be an economical alternative to create the shape from a semifabricated product such as bar or plate. Metal may be removed by chip formation or by less conventional, noncutting techniques (Fig. 9).

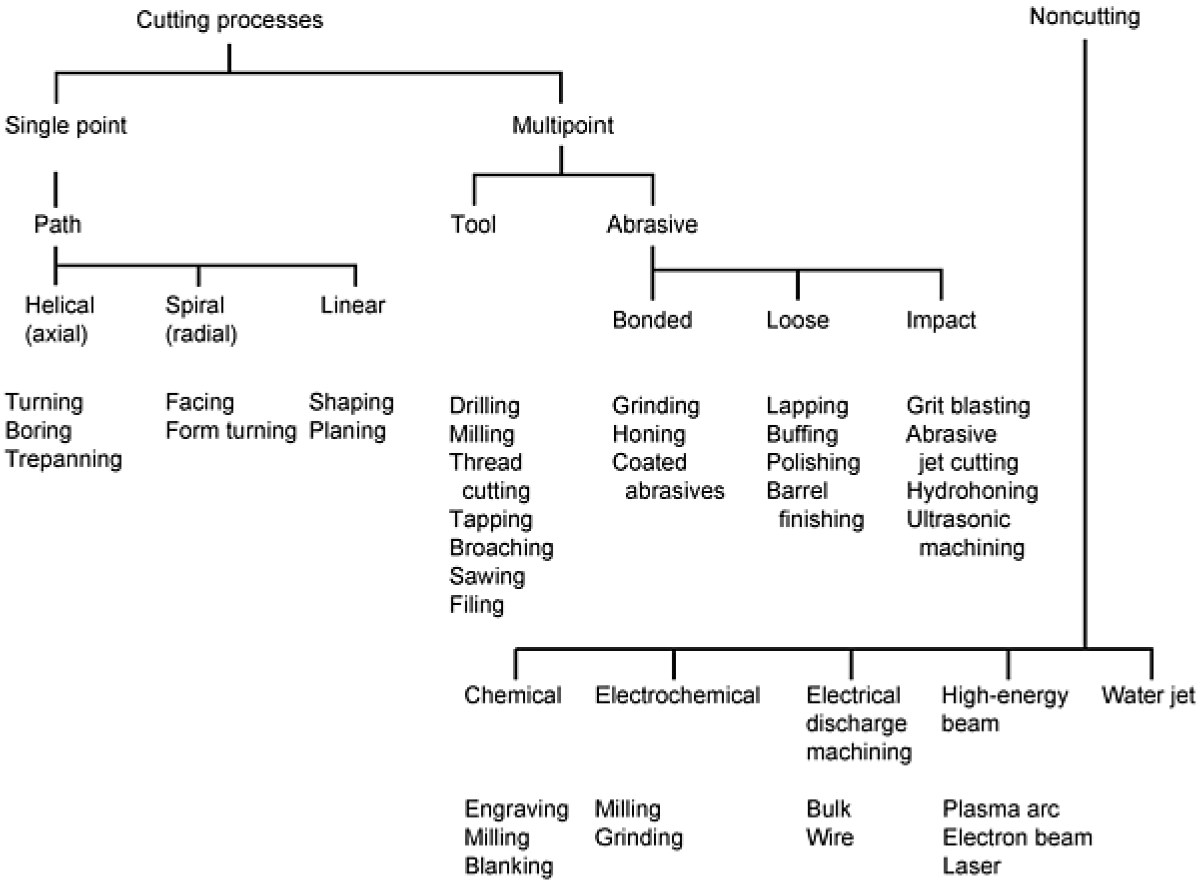

Fig. 9 General classification of metal removal processes

Metal Cutting

In metal cutting, excess material is removed by a controlled chip-forming process. The relative ease or difficulty with which material is removed is termed machinability. An alloy of good machinability can be cut at higher metal removal rates with acceptable tool life and will give better surface finish at lower cost. Some processes are more suitable for producing tight tolerances and finer surface finish, but the general guidelines should be interpreted with caution: in any given process, a hard, leaded brass will be easier to cut and will give better finish than a soft copper or a hard superalloy. Because the shape is generated by removal of excess material, there is basically no limit on section thickness except as influenced by deflection of the part under cutting forces. Because heat generation increases with cutting speed and power consumed (see Table 11 in the article "Relationship between Materials Selection and Processing" in this Volume), the choice of tool material has decisive influence. Great advances in metal removal rates have been made by the introduction of heat-resistant tools, tool coatings, and improvements in machine tools. The number of processes is large but can be reasonably well categorized (Fig. 9).

Single-Point Machining. The tool has a well-defined geometry with only one cutting edge, and the part shape is developed by control of the tool path. In turning on a lathe, the tool path is helical or spiral; hence the machined surface always has axial symmetry. Under manual or computer numerical control (CNC), complex shapes can be produced singly or in batches. The size range is enormous, from tiny shafts to generator rotors weighing hundreds of tons. Mass production with hard-programmed (cam-driven) screw machines may still be economical, although CNC is also being applied. On a planer or shaper the straight tool path creates essentially two-dimensional shapes.

Multi-Point Machining. The tool has two or more cutting edges of well-defined geometry. The tool path is simple in drilling, broaching, thread cutting, tapping, and often also in sawing and filing. It can, however, be complex in milling, and CNC milling machines with five axes of control are capable of producing the widest variety of shapes, including undercut shapes (Table 4), in a wide range of sizes. Multihead milling machines remove more than 90% of the material for wing surfaces of jet aircraft. Metal removal rates can be very high on highly machinable materials such as heat-treated aluminum alloys, using spindle speeds in the tens of thousands of revolutions per minute (high-speed machining). Milling can be an economical choice even for rapid prototyping and for making parts directly from a billet (hogging out airframe components can be competitive with forging).

Abrasive Machining. Chips are formed by random encounters with abrasive grit. Shape control is achieved by binding the abrasive into a grinding wheel, a honing stick, or onto a backing paper or cloth (coated abrasives). Originally used only for finishing to close tolerances and good surface finish, creep-feed grinding rates have increased to where the process can be competitive with chip-forming processes, although disposal of sludge may be a problem. Loose abrasives give dimensional control and surface finish in lapping but only surface finish in buffing, polishing, and barrel finishing. Metal removal with control of surface finish is the aim of impact machining processes.

Noncutting Processes

Noncutting processes are also called nontraditional machining processes and include etching, electrical discharge machining (EDM), and high-energy-beam processes. Common to all these processes is insensitivity to the mechanical properties of the metal, making them excellent candidates for the manufacture of tools and parts from heat-treated steel, superalloys, and other low-machinability materials.

Etching. Metal removal by chemical action (etching) has a long history in art as engraving, but it is a relative newcomer for metal removal (chemical milling) or blanking, as in producing copper circuit boards or large aluminum-alloy aircraft components. Dissolution of metal is accelerated by electrochemical milling or grinding. Surface finish can be very good unless one phase of an alloy resists dissolution.

Electrical discharge machining relies on electrical discharge between the workpiece and a shaped electrode (bulk EDM, indispensable for sinking many forging dies and injection molds) or wire (wire-EDM for two-dimensional and, under multiaxis computer control, three-dimensional shapes). Material is removed by controlled melting and vaporization. Surface finish is less fine than with chemical machining, but production rates are much higher.

High-energy-beam processes melt and vaporize the metal by highly concentrated plasma arc, electron beam (EB), or laser beam. Electron beam machining requires vacuum, which increases cost but also protects the metal.

Design guidelines are given in the article "Design for Machining" in this Volume.

Joining Processes

Some joining processes can be regarded as assembly processes, others properly belong among manufacturing processes. Thus, welding of a tube is clearly manufacturing; brazing a heat exchanger from welded tube is assembly. The same physical principles govern both.

Nonpermanent joints allow easy disassembly. Screw joints are long established; snap fits are enjoying great growth (especially with plastics); and shrink fits can be nonpermanent, mainly with metals. The focus in this article is on methods for creating permanent load-bearing joints (Fig. 10 and Table 5).

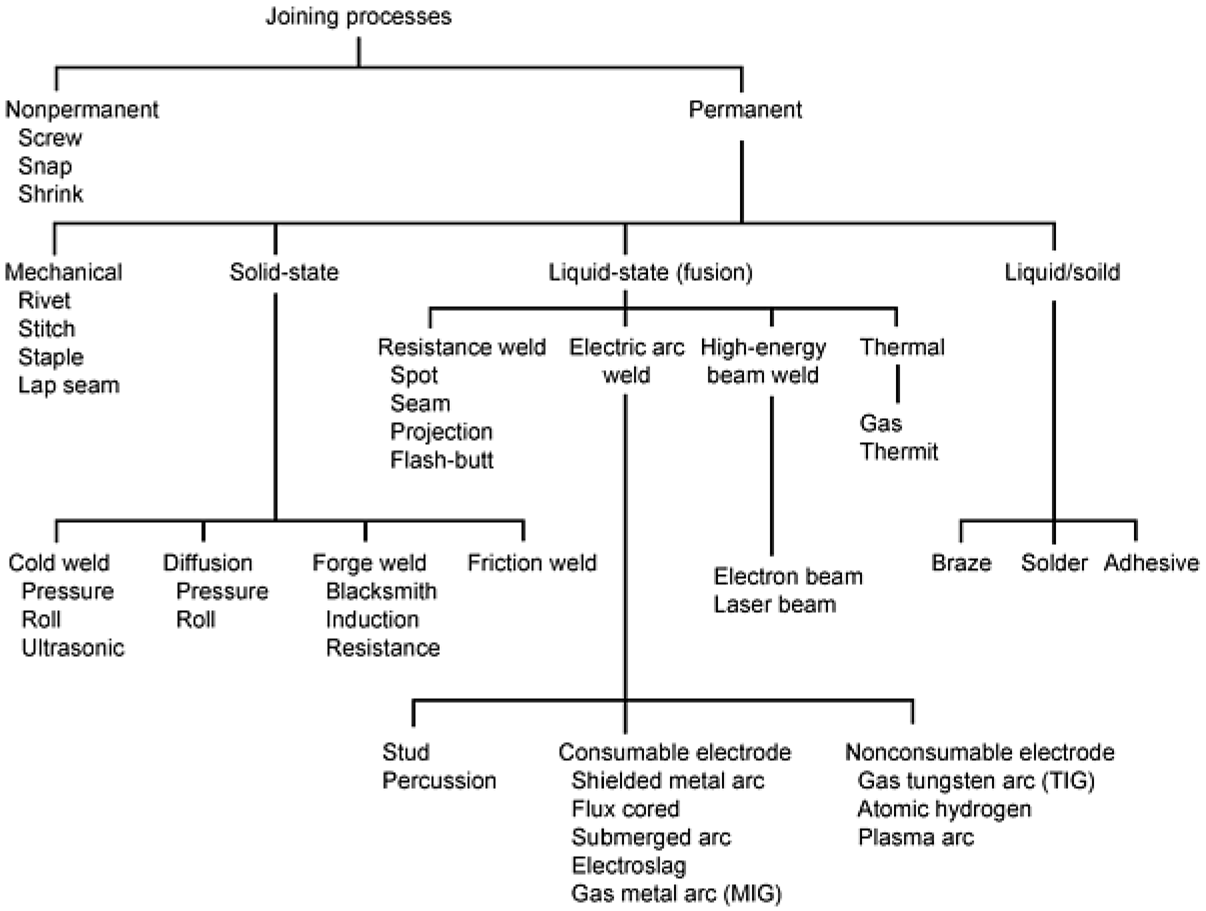

Fig. 10 General classification of joining processes (after Ref 16)

Mechanical Joining

No metallurgical bond is established with mechanical joining processes such as riveting, stitching, stapling, and lap seams; hence their design presents special challenges. In some applications they may be used in conjunction with an adhesive bond (rivets in airframe construction) or solder (lap seams in tubes).

Solid-State Welding

When perfectly clean surfaces are brought into intimate contact, interatomic bonds form a joint. Bond strength is greatest when the mating metals are mutually soluble, but good welds can be obtained with dissimilar, not otherwise weldable metals and with highly differing thicknesses.

Cold Welding. Sufficient pressure must be exerted to establish conformance of surfaces. Sliding and deformation accompanied by surface expansion are needed to break up oxides and other adsorbed films. Cold welding processes differ only in the method of providing these conditions. Complex tubular parts such as refrigerator evaporator plates can be made by depositing a parting agent in a pattern to prevent welding; after roll bonding the passages may be inflated.

Diffusion Bonding. Elevated temperature accelerates diffusion and thus the establishment of bonds. Superplastic forming of titanium alloys, combined with diffusion bonding, permits the production of complex shapes.

Forge Welding. As a generic term, it applies to bonding by deformation at hot-working temperature. Large surface extension in hot-roll bonding creates strong bonds for cladding, as in bonding copper-nickel surface layers to a copper core for some U.S. coins (dimes and quarters). Heating is highly localized in high-frequency induction and high-frequency resistance welding. Some melting may take place, but the melt is squeezed out by compression, as in welding tubes from roll-formed strip.

Friction Welding. Heat is produced by friction between a rotating and stationary part; again, some melt may form that is expelled together with oxidized metal. Localization of heat allows welding of dissimilar metals and of very different dimensions (e.g., a thin stem to a large head for an internal combustion engine valve).

Liquid-State (Fusion) Welding

A localized melt pool of the parent metal (autogenous weld) or of the filler and parent metal is formed and allowed to solidify. The weld metal has a cast structure of often complex composition, and if the temperature range of solidification is wide, it is prone to cracking in the presence of tensile stresses. Adjacent parent metal is affected by the rapid heating-cooling sequence, and properties in this heat-affected zone (HAZ) may deteriorate. Weldability is, therefore, highly specific to alloys (see the article "Relationship between Materials Selection and Processing" in this Volume). To maintain tolerances, distortion due to localized heating and cooling must be prevented or controlled during welding by the use of jigs and fixtures. Residual stresses lead to distortion after welding and are minimized by stress-relief anneal. Special techniques are used to mitigate problems arising from great differences in material thickness. Several sources of heat may be drawn upon.

Resistance Welding. After the two parts have been pressed together, electric current passes through the joint to heat and melt the interface. Pressure is kept on until solidification of the melt is complete. Spot welding is widely employed in building car bodies using welding robots. Projection welding is commonly used to join small parts. Seam welding is used for making beams and box sections. Flash-butt welding differs in that the current is switched on during the approach of surfaces, drawing an arc; the technique is extensively employed in making rings and chain links from bent sections.

Electric-Arc Welding. In stud welding, an arc is formed between one part and a projection on the other; in capacitor-discharge welding the energy is stored in a capacitor. Parts of different materials and dimensions can be welded. Consumable electrode welding uses a filler rod (electrode). Protection is provided by a coating that forms a slag and gas cover and can also supply alloying elements. Flux-cored wire allows continuous and mechanized operation. The flux is supplied as a powder in submerged-arc welding for horizontal welds, and a resistive slag pool protects the weld zone in electroslag welding of thick plates. Protection is given by an inert gas in gas metal arc (previously referred to as metal inert gas, MIG) welding, suitable for welding in all positions. Autogeneous welds are produced by nonconsumable-electrode or gas tungsten-arc (tungsten inert gas, TIG) welding. Very high temperatures are created in plasma-arc welding. Seam-tracking robots allow automation even when the weld is to follow a complex path.

Thermal Welding. Heat is provided by an oxyfuel gas flame, mostly for manual welding, or by a thermit reaction for joining heavy sections such as rails. Portability is a great advantage.

High-Energy-Beam Welding. Highly concentrated beams of electrons impinge on the weld zone in electron-beam (EB) welding. When the workpiece is enclosed with the gun, the high vacuum required protects the surfaces, but increases cost and lowers production rates. Out-of-chamber welding is also possible. Gas (CO_2) or solid-state (Nd-YAG) lasers have seen increasing application for joining not only difficult metals and delicate parts, but also sheets of different thicknesses for "tailored" blanks used in autobody construction. All high-energy-beam processes have the advantage that the HAZ is small.

Liquid-Solid-State Bonding

Only the filler metal is melted, and joint strength relies on adhesion to the surfaces. Therefore, absence of interface films and wetting of surfaces are absolute requirements. Fluxes, protective atmospheres, or vacuum are applied. Control of gap is critical to ensure filling by capillary action.

Strong joints are formed by brazing with a relatively high-melting alloy, such as copper or silver alloys for steel and aluminum-silicon alloys for aluminum, often in the form of a cladding on one of the surfaces. Hundreds of parts may be simultaneously joined in products such as heat exchangers. Joining with low-melting lead-tin or, more recently, lead-free solders creates a weaker joint that is suitable for many applications, including radiators, water circuits, and electrical connections.

Adhesive Bonding. Structural adhesives are a special class of polymers, finding increasing application not only in the aircraft industry, but also for automobiles and consumer goods. Joint design must ensure the absence of out-of-line stresses that would cause peeling or cleavage. Extensive coverage is provided in *Adhesives and Sealants,* Volume 3 of the *Engineered Materials Handbook* published by ASM International.

Guidelines for joint design are given in the article "Design for Joining" in this Volume.

Processing of Ceramics and Glasses

The variety of ceramics is extremely large and the processing routes are highly varied. A simplified overview of the principal methods is given in Fig. 11, and Table 6 shows some characteristics. Starting materials are natural minerals or highly sophisticated manufactured products. After comminution by dry or wet milling, processing sequences diverge for crystalline ceramics and amorphous glasses.

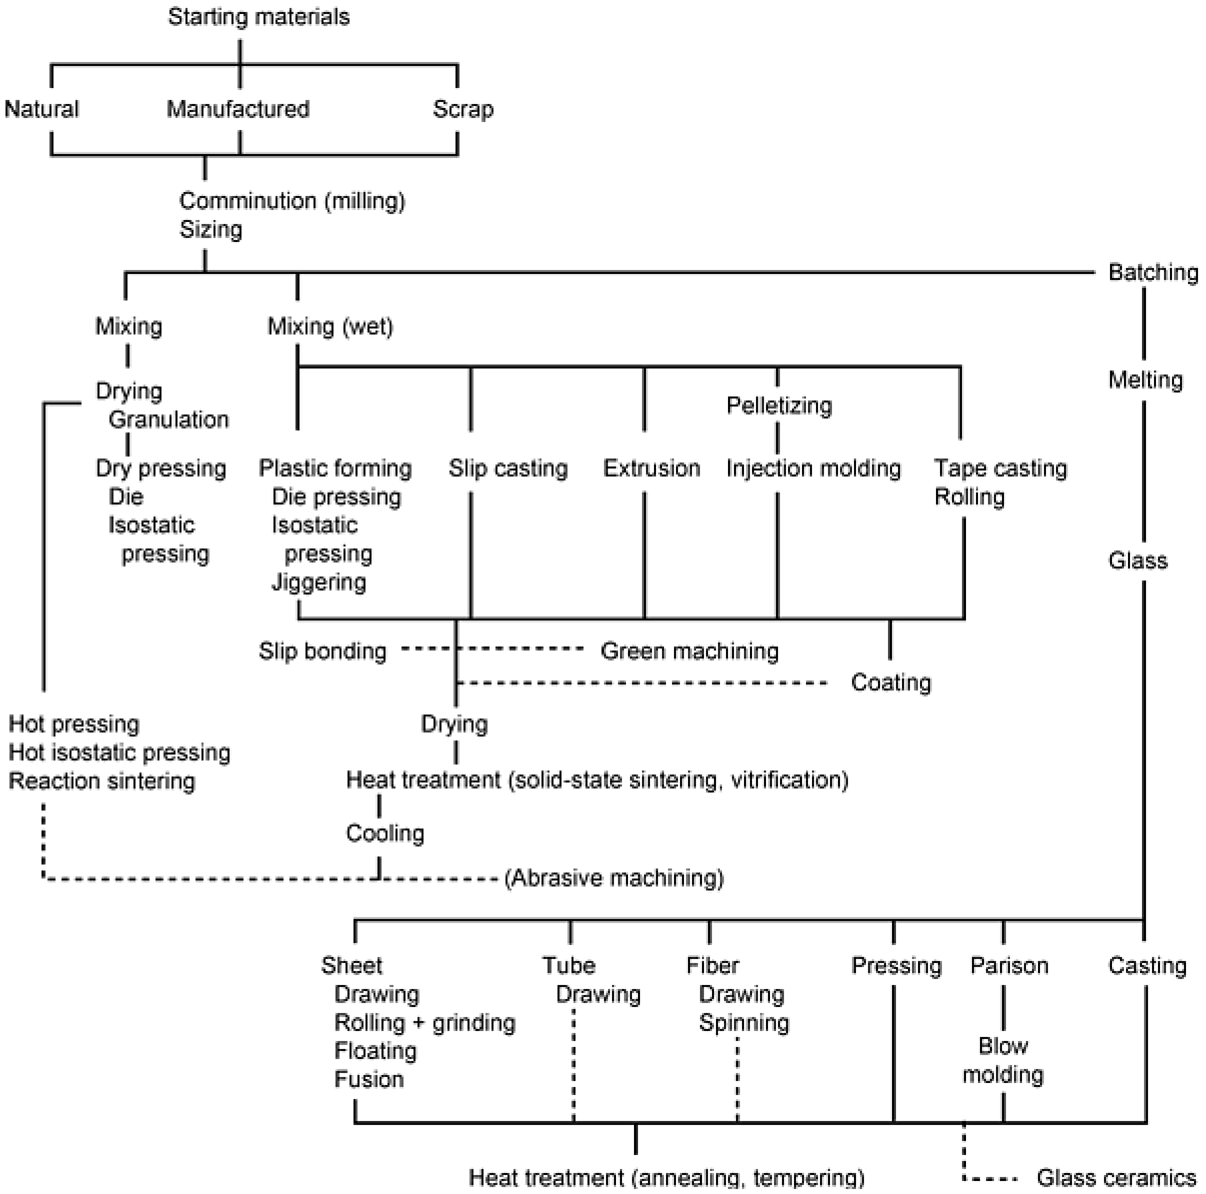

Fig. 11 General classification of ceramics processing

Ceramics Processing

Crystalline ceramics are more or less free-flowing powders. When mixed with binders and lubricants (and possibly after granulation), they can be treated as metal powders are, by dry pressing in dies or by isostatic pressing. With the addition of some water, ceramic powders behave as plastic bodies and can be formed with techniques similar to those used for metals, such as pressing or isostatic pressing. Screw extrusion offers high productivity for two-dimensional shapes. Forming with a rotating template (jiggering) is unique to ceramics. More water makes a slurry (slip) that can be cast inside a plaster mold. As the porous mold absorbs water, a solid layer forms and the excess slurry is drained off to leave a body of reasonably well-controlled wall thickness and high shape complexity (e.g., toilet bowl). Several parts can be joined by slip bonding.

Mixed with resin, the ceramic can be injection molded for near-net shapes or cast into tapes that are rolled up and treated as metal strips (e.g., for ceramic substrates of microelectronic devices).

Shape details can be developed and closer tolerances held by machining the green body. A crucial stage in all ceramic processing is removal of excess liquid (drying) or binder. During subsequent firing, bonds are established by solid-state sintering and possibly by melting (vitrification) at grain boundaries. Several processing steps are by-passed by HIP, by

reaction sintering accompanied by chemical reactions, and by direct deposition of ceramics on metal or ceramic substrates by chemical vapor deposition (CVD) and physical vapor deposition (PVD).

Many ceramics are subject to cracking when exposed to thermal shock and must be cooled in a controlled manner. Removal of binder and buildup of stresses due to nonuniform heating and cooling set a practical limit to the size of ceramic parts. Surface finish and tolerances are controlled by the choice of particle size and by allowing for shrinkage. Tightest tolerances require final shaping by machining. Because ceramics are generally hard, only abrasive machining with a yet harder ceramic (most often, diamond) is feasible. High-energy beam machining, such as laser cutting, drilling, and scribing are widely practiced.

Glass Processing

In contrast to crystalline ceramics, a glass body is a single, giant three-dimensional network of an oxide (most frequently silicon dioxide, SiO_2) modified by other oxides. Glass can be regarded as a metastable, undercooled liquid of extremely high viscosity, exhibiting elastic-brittle behavior. Upon heating above the glass transition temperature (T_g), glass becomes a viscous or somewhat viscoelastic material which, because of its high strain-rate sensitivity (high *m*-value, Eq 1), can be formed in tension without localization of a neck. This allows processing with free surfaces, resulting in a very smooth finish.

Glass sheet is made by several techniques:

- Drawn for lower-quality requirements (window glass)
- Fusion drawn for higher quality
- Floated on a tin bath for plate and mirror glass

In earlier times, plate glass was rolled and then ground for flatness and surface finish. Continuous tubes and fibers (including fibers for glass-reinforced polymers and for fiber optics) are produced by stretching above T_g. Large quantities of glass wool are made by spinning at higher temperature.

Pressing in dies is practiced for mass production, but the die must be free of surface defects because all detail is faithfully reproduced. The same applies to blow molding of preforms (parisons) into bottles and lamp bulbs; die coatings that generate steam ensure a good surface. Casting is limited to special applications such as telescope mirrors. Special vapor-deposition processes are needed to produce bars of exceptional purity for drawing into optical fiber.

As with all ceramics, cooling rates are critical. Cooling is followed by annealing for the relief of internal stresses and if, required, by quenching to induce compressive surface stresses (physical tempering). Similar results are obtained by replacement of ions in the surface (chemical tempering). Extended heating converts the glass into a fully dense crystalline ceramic (glass ceramics). Glasses are applied also as glazes to ceramics and as enamels to metals. The relatively low hardness of many glasses permits extensive machining by abrasive processes. Chemical machining (etching with hydrofluoric acid, HF) has long been used.

Manufacturing Processes and Their Selection

John A. Schey, University of Waterloo

Polymer Processing

Compared with metals, polymers exhibit a much greater variety of behavior that is further complicated by the extensive use of fillers and reinforcing particles in many plastics. There are, nevertheless, many similarities to processes practiced with metals and glasses. Differences arise from the molecular structure of polymers as opposed to the atomic structure of metals. A general overview is given in Fig. 12 and process characteristics are listed in Table 7.

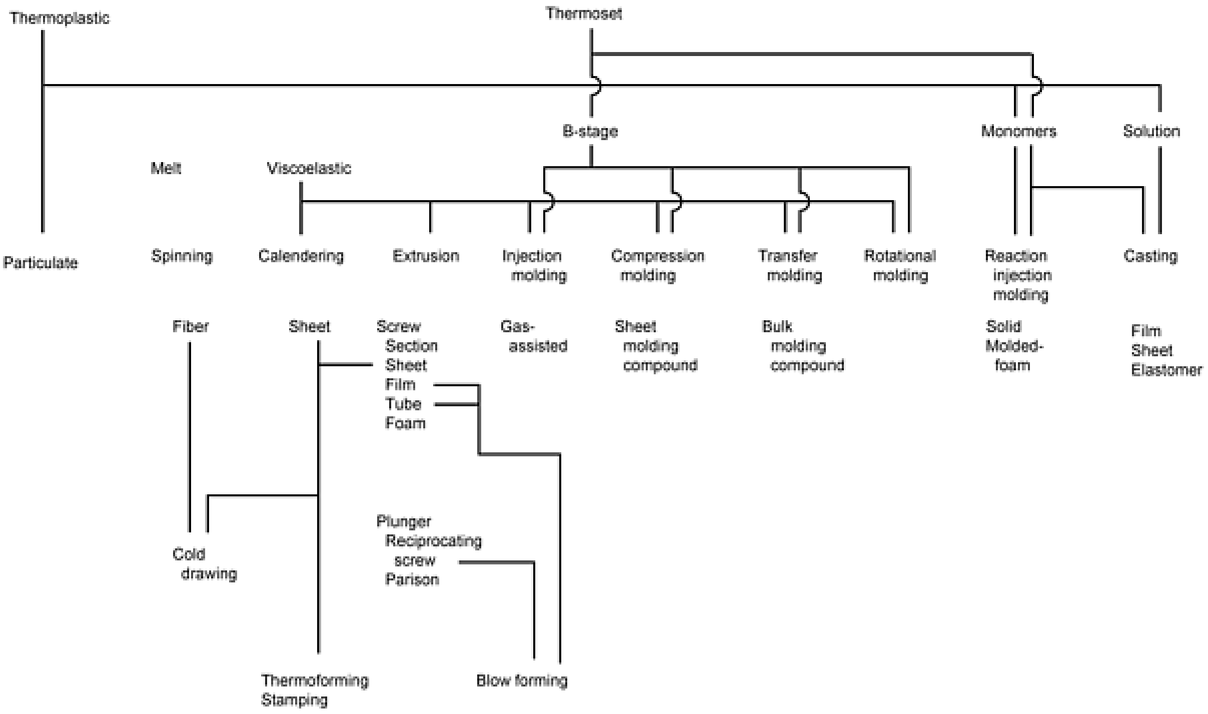

Fig. 12 General classification of polymer processing

Types of Polymers

Three basic groups may be distinguished: thermoplastics, thermosets, and elastomers.

Thermoplastic Polymers. Most often, polymerization takes place in a primary process. The resulting polymer, usually in the form of particulates (pellets), is formed into final shape by consolidation at elevated temperature, and the shape is fixed by cooling below the T_g. The cycle may be repeated, allowing recycling of these plastics. Deformation is possible by moving polymer chains relative to each other. Above their melting point (T_m), low-molecular-weight polymers exhibit Newtonian or near-Newtonian flow; with increasing molecular weight and shape complexity, flow becomes non-Newtonian but strain rate is still highly dependent on the imposed stress. Strain-rate sensitivity (in terms of Eq 1, a high m-value) permits large tensile deformation. Most processing takes place in the solid state, just below T_m for partially crystalline polymers and above the T_g for amorphous polymers. Flow is viscoelastic and, upon releasing the forming stress, the part would regain its original shape. For the part to retain its shape, it must be cooled well below T_g. Thus, even though compression molding of thermoplastic polymers appears to be very similar to closed-die forming of a metal, cycle times are longer and the part has oriented molecules reflecting the direction of material flow. Properties in the transverse direction are lower, much more so than with metals. Shrinkage is higher too, especially with crystalline polymers, and contraction during cooling can be anisotropic. This, combined with slower cooling of thicker sections, induces residual stresses, and the part will warp.

Thermosetting Polymers. Polymerization takes place during manufacture of the part, creating a single, nondeformable, giant molecule. Polymerization may proceed in stages: the primary processor creates a linear, so-called A-stage resin and adds fillers, colorants, and catalysts to form a B-stage resin that is delivered to the manufacturer of finished products. This resin is thermoplastic for a limited time at elevated temperature, and it can be formed while cross-linking and polymerization take place. Thereafter, no shape change is possible; the plastic cannot be recycled. Shrinkage and differential cooling set up stresses that may lead to fracture in brittle plastics.

Elastomers. The part is again a single giant molecule, but it is formed by cross-linking the molecules of thermoplastic polymers. Once formed, the shape can be changed by loading, but is regained upon unloading.

Effects of Additives, Reinforcements, and Surface Topography

Additives. The properties of polymers are greatly changed by additives, such as antioxidants, flame retardants, plasticizers (for thermoplastic polymers), solvents, dyes, pigments, lubricants, and mold-release agents. From the manufacturing point of view, most significant are fillers. Particulate fillers are added for technical reasons (reduced shrinkage, less distortion, increased mechanical properties, color, etc.). Strictly speaking, reinforced polymers are composite structures, but--in keeping with general usage--plastics with chopped-fiber reinforcement, processed as though they were of a homogeneous mass, are included in this present discussion, while continuous-fiber-reinforced polymers are treated below.

Reinforcements. For reinforcements to have a beneficial effect, they must be wetted by the polymer so that load is transferred to them. Very short fibers and flakes increase the flexural modulus, but at the expense of impact resistance. Longer fibers increase impact strength, but properties become directional if the fiber is free to move during molding. Most importantly for crystalline and semicrystalline thermoplastic polymers, creep is greatly reduced to allow their application at temperatures close to the melting point, to the extent that many underhood engine components are now made of plastics.

Surface topography of plastics is highly variable. When the shape of a pure polymer is given by contact with a die, the die surface finish is faithfully reproduced. This is exploited in giving a controlled finish (pattern, textured surface) for aesthetic and/or technical purposes. The pattern must allow release of the part from the mold; thus typically 1° of draft is given for every 0.025 mm (0.001 in.) of texture depth. Shrinkage results in loss of surface quality. Fillers that reduce shrinkage are beneficial, but reinforcements can stand out of the surface of a high-shrinkage polymer. Surfaces not in contact with a die can be very poor, especially with fiber reinforcement.

Processes Restricted to Thermoplastic Polymers

In these processes, the shape is given while the polymer is heated, and shape is fixed by cooling below T_g.

Powder Processing. Some very long-chain polymers (polytetrafluoroethylene, ultrahigh molecular weight polyethylene) do not soften sufficiently to allow shaping and are compacted from powder by techniques similar to those used in P/M (cold pressing followed by sintering; hot pressing; hot extrusion).

Melt Processing. Techniques are based on viscous flow above T_m for crystalline and well above T_g for amorphous polymers. Highest temperatures are needed for melt spinning of fibers. Calendering is akin to rolling and produces sheet. Extrusion with continuously rotating screws is suitable for sheet, structural sections, tube, and thermoplastic foam products; a reciprocating screw or plunger is used for parisons. Because there is always some viscoelasticity, the material swells as it emerges from the die, and this must be taken into account to achieve the requisite tolerances.

Rubbery-State Processing. Around T_g (in the glass-transition temperature range), polymers are viscoelastic, and their high strain-rate sensitivity (high m-value, Eq 1) allows tensile deformation without localized necking. Thus, fibers are cold drawn for higher strength, sheet is stretched (thermoformed) by vacuum or pressure or it is stamped in matching dies, tubes are blown in diameter to give thin films, and parisons are blown into bottles and other closed-ended products.Unidirectional deformation results in the alignment of molecules, giving high strength in the longitudinal and often poor properties in the transverse direction. Biaxial stretching is needed for balanced properties, as is done for bottles blown from parisons.

Processes for Both Thermoplastics and Thermosets

For thermoplastics, the heated polymer is cooled in the mold. For thermosets, the mold is heated to promote polymerization (unless a catalyst can do it alone); the precursor can be cold or, if it is a B-stage resin, heated to make it flow. Fillers and, especially, fibrous reinforcement result in marked directionality.

Injection Molding. This is similar to die casting of metals, but the plastic is injected by a reciprocating screw or, less frequently, a plunger. The split die must be held closed during injection, and the press size sets a limit to the maximum allowable projected area. Gating and feeding are important, especially with polymers of high shrinkage. Filling of sections with various thicknesses (ribbed sections) can be promoted with the injection of gas (gas-assisted injection molding), which creates hollow ribs and forces plastic into thin sections. The need to retract solid cores limits shape complexity, although low-melting tin-bismuth alloy cores are used in the lost-core process to create shapes as complex as those made with lost-wax (investment) casting of metals, such as air intake manifolds.

Compression molding is similar to closed-die forging in that the plastic is deformed between mating dies. The preform can be shaped to ensure the best orientation of fillers. In sheet molding compounds (SMC) the chopped reinforcing fibers (random or oriented) are sandwiched between polymer paste layers. Large, exposed autobody panels, as well as load-bearing members, are formed with high surface quality. Bulk molding compounds (BMC) use shorter fibers in smaller concentrations.

Transfer Molding. A premeasured amount of polymer is placed in the transfer pot and pressed into the die; shear heating in the orifice helps to fill intricate details and to flow around delicate inserts, as in connectors for electronics.

Rotational Molding. A relative of slush casting. The mold is rotated around two axes to spread the polymer, for small squeeze bulbs to large containers. This is the only process capable of making totally enclosed hollow parts (shape T5).

Reaction Injection Molding (RIM). The reactants are injected into the mold at high velocity through an impingement head that ensures thorough mixing. The plastic polymerizes in the mold; because pressures are low, tooling and machine cost are lower than in injection molding.

Casting of polymers refers to filling a mold by gravity, using prepolymers or monomers that react in the mold, as for sheet casting or encapsulation in polymethyl methacrylate or potting in thermosets. Because pressure and temperature are low, even flexible rubber molds can be used, allowing a greatly increased shape complexity relative to metals. Slush casting of plastisols (i.e., a suspension of PVC particles in a plasticiser) is widespread, often by rotational molding, for industrial as well as consumer products (snow boots).

Machining of Plastics

Even though plastics are generally weaker than metals, this does not mean that they are easier to machine. Special tools are needed to prevent localized melting, smearing, or cleaving in coarse fragments, but machining at high rates with acceptable surface finish is then possible. Reinforced plastics can be hard on tools and carbide or diamond tools are extensively employed.

John A. Schey, University of Waterloo

Manufacture of Composites

By definition, a composite is made up of two or more materials that retain their identity and exhibit an interface between one another. In this sense, all coated and clad metallic products, fiber-reinforced polymers, and many ceramics are composites. In the narrower sense used here, the composite is created by embedding long or continuous fibers in a matrix, which may be a plastic, a metal, or a ceramic. In all cases, the critical issue is bond strength at the interface, so that stresses are transferred to the fiber.

Polymer-Matrix Composites

Filled plastics are composites, as discussed in the preceding section. This section concerns plastics reinforced with long fibers, such as glass, carbon, boron, and other fibers. Manufacturing processes (Fig. 13) differ chiefly in the sequence of operations and in the size and shape complexity permitted. In many instances, metal assemblies formed of several parts can be replaced with a single-piece, integrated polymer-matrix composite part.

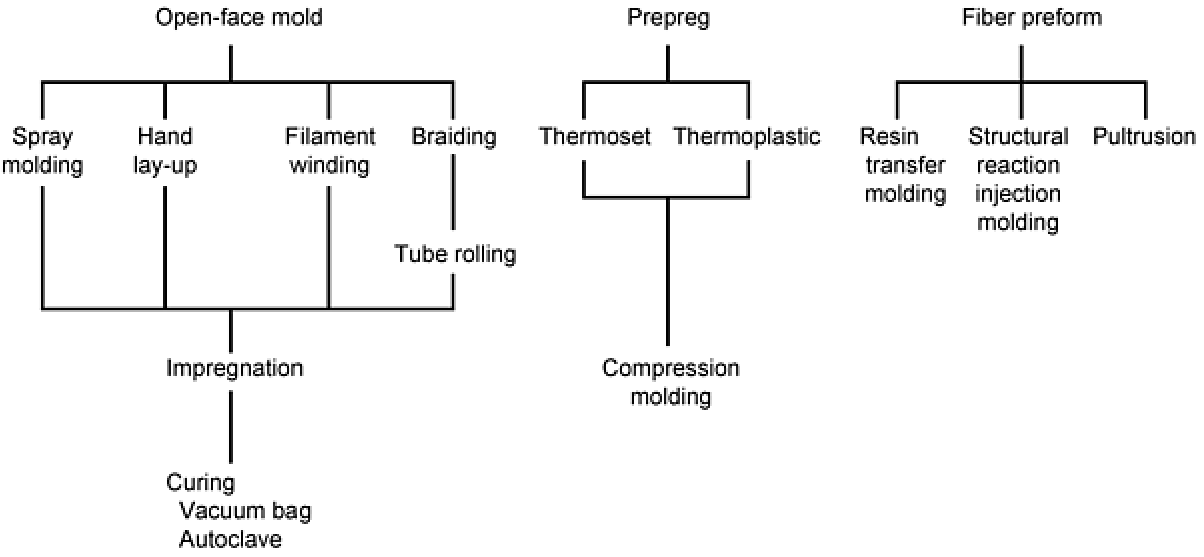

Fig. 13 General classification of processes for polymer-matrix composites

Open-Face Molding. In spray molding, the chopped fiber is mixed with the resin and sprayed on the form. In hand lay-up, the fiber is positioned first and then liquid resin is applied, often by hand. Optimal fiber orientation is achieved by filament winding (often under computer control) or by placing a cloth or braided preform. Curing takes place in air or, to reduce voids, under a vacuum bag (a cover). For higher properties, curing is performed in an autoclave at elevated temperature, under pressure or vacuum. While tolerances and surface finish are not the best, there is great freedom in size and shape complexity; for example, for complete boat hulls and filament-wound rocket motor cases. Almost totally closed shapes can be made if the mandrel is dissolved after curing the resin.

Prepreg Resins. As the name implies, the reinforcing fibers are preimpregnated with resin. Fibers may have unidirectional or multidirectional orientation or may be woven into a cloth. Prepregs used in aerospace applications

contain carbon fibers in an epoxy or polyimide resin matrix. Sheet molding compounds of polyester or vinyl ester resin, reinforced with glass fiber, are extensively used in automotive and appliance manufacturing. Prepreg sheets can be rolled up into cylindrical or conical tubing. Resin-impregnated fiber bundles (prepreg tow) are useful for filament winding. Prepregs are used also for the construction of relatively low-cost tooling for other polymer processes.

Injection Molding. The process differs from injection molding of reinforced polymers in that the reinforcement is placed in the mold, the mold is closed, and only then is the resin injected. Such resin transfer molding (RTM) requires relatively low pressure, thus foam cores may be placed (and left) in totally enclosed sections of the part. There is greater freedom in shapes than with compression molding or metal stamping as, for example, in making deep spare tire wells. In structural reaction injection molding (SRIM), the components of the resin are mixed in a high-pressure mixing head from which the mixture flows at low pressure into the mold. Viscosity is higher than for RTM resins; hence flow distances are limited to about 1 m (3 ft) from the inlet gate.

Pultrusion. A reinforcing fiber bundle (roving) is impregnated with a thermosetting resin and drawn through a heated die to make bars, sections, and tubes. Most often, glass fiber is reinforced with polyester or vinyl ester; for higher performance, aramid or carbon fibers are embedded in epoxy.

Metal- and Carbon-Matrix Composites

Metal-Matrix Composites (MMCs). Most frequently the matrix is a light metal (aluminum or magnesium), although titanium, copper, and superalloys are also used. The reinforcing fiber can be boron, tungsten, a ceramic such as silicon carbide (SiC) or alumina (Al_2O_3) or graphite (carbon). Processing of continuous-fiber-reinforced composites follows techniques used for polymer-matrix composite manufacture (infiltration, pultrusion) or metalworking (investment casting, hot isothermal rolling, diffusion bonding). Discontinuous-fiber reinforcement allows casting, squeeze casting, hot extrusion, hot forging, and P/M techniques.

Carbon-Matrix Composites. Carbon fiber is embedded in a carbon matrix, produced by pyrolysis of a resin or tar. Shapes are created from prepregs or by infiltration of fiber forms.

Ceramic-Matrix Composites

Glass, alumina, silica, or silicon nitride matrix is reinforced with refractory metal (molybdenum, tungsten, tantalum, niobium) or carbon fibers or ceramic (SiC) whiskers. Hot pressing, cold pressing and sintering, slip casting, plasma spraying, and other processes can be used.

Many processes for the manufacture of composites are under intense development, and their scope is continually being expanded; hence neither size nor shape limitations are set. Costs and productivities are also changing; some systems in the development stage are extremely expensive, while others have entered the production stage (e.g., aluminum-alloy diesel engine pistons reinforced with alumina or silicon carbide fibers or whiskers).

Machining of Composites

Machining of composites presents special challenges because many fibers are abrasive, reducing tool life, and delamination and fiber/matrix pull-out are always dangers. Ideally, the part would be made to net shape, but this is not often possible. Such finishing as is necessary is then done with special drills, diamond-coated circular saws, and special techniques such as water-jet cutting, water-jet abrasive cutting, and laser machining.

Manufacturing Processes and Their Selection

John A. Schey, University of Waterloo

Manufacturing Process Selection: Example

The foregoing discussion has shown that, more often than not, several processes are potential candidates for making any one part. Indeed, many of these processes coexist for the manufacture of parts that meet the product specification (design)

requirements. This is particularly true of parts of relatively little shape complexity, as demonstrated by the example of a spool-shaped part shown in Fig. 14(a) (shape T2, Fig. 1). Options will be a strong function of material, size, tolerances, and production volume.

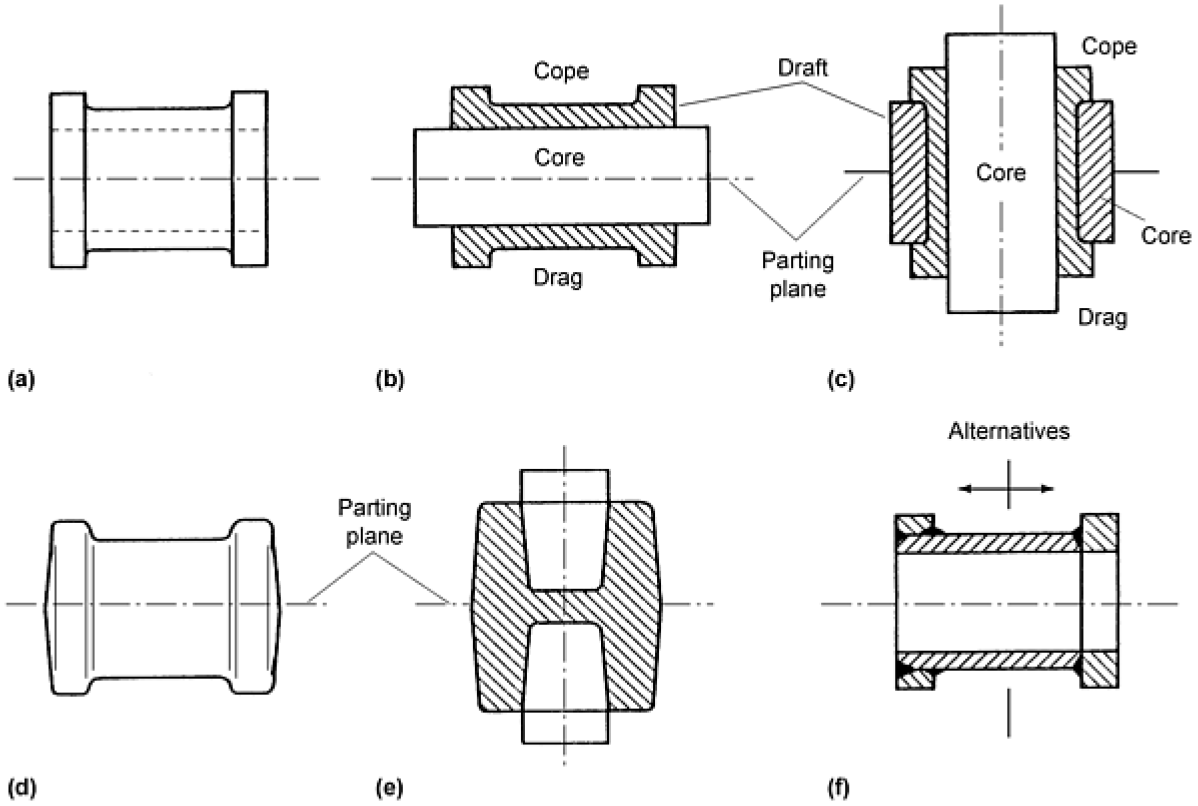

Fig. 14 Some possible methods for making a spool-shaped part. (a) Machining (turning) from a solid bar. (b) Casting in horizontal position. (c) Casting in vertical position. (d) Forging in horizontal position. (e) Forging in vertical position. (f) Welding a ring (left) or flange (right). Source: Ref 16

For illustrative purposes, assume that the part is made from a ferrous material, with a minimum tensile strength of 180 MPa (40 ksi); ductility is of no major concern. Take first the following dimensions: bore diameter 50.00 mm (2.000 in.), wall thickness 2.5 mm (0.1 in.), flange diameter 75.0 mm (3.0 in.), flange width 10 mm (0.4 in.) and total length 100.00 mm (4.000 in.). Tolerances of ±0.025 mm (±0.001 in.) apply only to the bore diameter and total length. For a tolerance range of 0.05 mm (0.002 in.) over a 25 mm (1 in.) dimension, only a machining operation can provide required quality (see Fig. 5 in the article "Overview of the Materials Selection Process" in this Volume). This applies even more to the larger dimensions of the part. Because finish machining is needed irrespective of the method of manufacture, there is great freedom in choosing the initial process for creating the shape.

Principal Options. Seven options are described below.

Option 1. The shape is suitable for turning on a lathe (Table 4). Machining from a solid bar (Fig. 14a) results in a cutting-off loss of 6 mm (0.25 in.), and material utilization is only 18%. Starting with (a much more expensive) tube of 46 mm (1.85 in.) inside diameter, material utilization increases only slightly to 25%.

Option 2. Casting is feasible by all expendable-mold processes (Table 1). Casting in a horizontal position (Fig. 14b) requires an inexpensive cylindrical core. With a machining allowance of 2 mm (0.08 in.) on all surfaces, wall thickness becomes 6.5 mm (0.26 in.); this allows for possible eccentricity of the core. This thickness has to be fed over a distance of 76 mm (3.04 in.); according to Fig. 2, this should be possible even for a steel casting but, in view of the modest strength requirement, a nodular cast iron will do. Material utilization increases to 37%.

Option 3. Casting in a vertical position (Fig. 14c) complicates the mold but allows bottom feeding. In view of the small size of the part, the benefit is not worth the expense.

Option 4. If the strength requirement were raised to the point where cast iron is insufficient and, especially if the part is exposed to fatigue loading, a higher grade of nodular cast iron or cast steel could be considered. Forging also becomes an alternative. Forging in a horizontal position (Fig. 14d) saves little material and the flash forms at a position where the flow lines create a potential weakness under an axially rotating load.

Option 5. Forging in a vertical position (Fig. 14e) gives poor material utilization, and fiber orientation is still not optimum. Forging on a horizontal forging machine creates, however, a part with favorable material flow, very close to the finished shape, and machining allowances could be reduced. The tooling with sliding insert would, however, be fairly expensive.

Option 6. Powder metallurgy by die pressing could be used to produce a tube, with an outside diameter equal to flange diameter and an inside diameter equal to bore less machining allowance. Because there are flanges at both ends, the reduced outside diameter cannot be directly pressed, and the economy of the process is doubtful. Isostatic pressing in a deformable mold would come much closer to final shape.

Option 7. In principle, the part could be made by welding a ring (Fig. 14f, left) or flange (Fig. 14f, right) but finish machining would still be required. It is highly unlikely that this method would be competitive.

Choosing among Options. The final choice would most likely come down to machining from the solid for small-lot production and casting or horizontal upsetting for larger production volumes. Economies would change if the part were much longer, but with the same flange: upsetting of tube (pipe) ends or welding flanges onto a tube would become much more attractive.

Increasing the flange diameter to 100 mm (4.0 in.) would change the evaluation. Machining from a bar again gives only 18% material utilization, and a thick-walled tube is not worth considering. Casting becomes a clear favorite with 56% material utilization. Horizontal upsetting of the flange from 56 mm (2.2 in.) to 100 mm (4.0 in.) diameter is possible, but stretches the capabilities of the process (material has to be gathered in several die cavities).

Increasing the length of the part with the larger flange makes the machining option less favorable. Casting is still attractive. Horizontal upsetter work is feasible only to a certain length (typically, a length-to-hole diameter ratio under 4), although a solid spool could be forged. Assembly by welding may be the most economical, depending on the cost of tubing. Cold-drawn tube would eliminate the need for machining the bore, provided that welding were performed without causing distortion or loss of properties.

In general, the range of process options is narrowed with increasing shape complexity and, as shown by the above example, with increasing differences in dimensions among various portions of the part. It may then be necessary to return to the design stage and consider alternative geometries and material options.

The number of possible processes would increase greatly if the restriction on the material (ferrous alloy) were removed and the strength criteria were relaxed, because both nonferrous materials and reinforced plastics would become viable candidates.

A detailed examination of alternatives for cutting sheet materials (Ref 22) illustrates the very broad range of processes that would have to be considered even for a relatively simple task.

Modeling of Manufacturing Processes

Anand J. Paul, Concurrent Technologies Corporation

Introduction

MANUFACTURING PROCESSES typically involve the reshaping of materials from one form to another under a set of processing conditions. To minimize the production cost and shorten the time to market for the product, all iterations in terms of an appropriate set of operating conditions should not be done on the shop floor. Predictive models need to be used generously to perform numerical experiments to give an insight into the effect of the operating conditions on the properties of the final product.

Process models must be able to build the geometry of the product/process that is being modeled, accurately describe the physics of the process, and be able to analyze the results in a way that is comprehensible by manufacturing engineers. There are several types of models that are used by the industry. These include models used as a tool in the course of scientific research, models that are very generalized in nature and can be applied to a wide variety of processes, but may not be able to address the nuances of any one process, models that are very specific in nature and can address a narrow range of operating conditions, models that rely on gross phenomena and are about 90% accurate but take only 10% of the execution time or more accurate models. Irrespective of the complexity, most models are used to gain one or more of the following advantages:

- Reduce iterations on the shop floor
- Optimize an existing process
- Understand an existing process better
- Develop a new process
- Improve quality by reducing the variability in the product and process

Anand J. Paul, Concurrent Technologies Corporation

Classification of Models

The following points need to be considered in order to classify modeling problems:

- The physical phenomena affecting the process under consideration
- Mathematical equations describing the physical process
- Data needed to solve the equations
- Numerical algorithm to solve the equations given the boundary conditions and the constitutive behavior
- Availability of the software to provide answers

One of the most common classification methods is by type of process or physics. This means that one must identify the major phenomena occurring in the process, for example, convection, radiation, chemical reaction, diffusion, deformation, and so forth. Once the phenomena has been identified, the process needs to be defined in terms of mathematical equations, typically partial differential equations. These equations are dependent on time, space, field variables, and internal states. Ordinary differential equations can be used if the problem can be simplified so that the shape is not important and a lumped-parameter model can be used. Several people have used lumped-parameter models for various materials processes (Ref 1, 2).

The requirements for particular data and the way in which it is gathered is an important step in the construction of a model. Researchers typically play down this step as an "industrial implementation detail." This means that the rest of the model needs to be robust and accurate before data are needed. Once accurate data are available, the result of the modeling effort will be good too. On the other hand, industrial practitioners place a greater emphasis on data gathering because they know the difficulties and time involved in gathering data on production-scale equipment.

Numerical algorithms to solve the differential equations consist of meshed-solution methods and lumped-parameter models. The major meshed-solution models consist of finite differences, finite elements, and boundary methods. Each of them is more appropriate for different types of equations and boundary conditions. Within these methods, one can use a structured or an unstructured mesh. Structured meshes are created by using rectilinear, bricklike elements. It is easy to use this type of mesh; however, fine geometry details may be missed. Unstructured meshes can be of any shape--tetrahedra, bricks, hexahedral, prisms, and so forth. Many of the disadvantages of using a structured mesh are eliminated through this type of a mesh.

Lumped-parameter models may help in understanding the effect of certain parameters on the process as along as the problem formulation does not change. These models do not model spatial variation directly, and the parameters may or may not be physically meaningful in themselves.

Choice of the appropriate software is an important aspect of the usefulness of the model. Almost without exception, research process models and all commercial software can be written directly in a third-generation language (Fortran, Lisp, Pascal, C, C++). User interfaces can be derived from various libraries. Because of the large number of calculations necessary to get the desired degree of detail, models may require parallel computing hardware for cost-effective solutions. Software developed for this has to be able to run and make use of the parallel-processing capabilities of the hardware.

Models for manufacturing processes can be classified in two primary ways, as shown in Fig. 1. One classification scheme considers whether the model is on-line or off-line; the other considers whether the model is empirical, mechanistic, or deterministic.

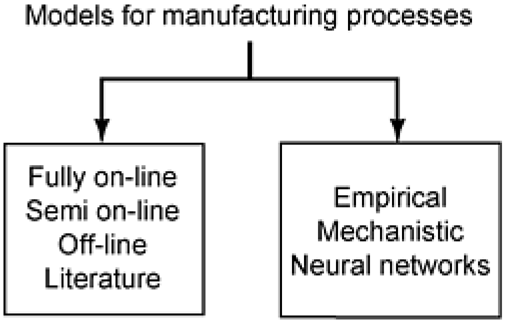

Fig. 1 Classification of models for manufacturing processes

Fully on-line models are part of the bigger process control system in a plant. Sensors and feedback loops are characteristics of these models. They get their input directly from the system. These models implement changes in the plant on a continuous basis (Ref 3). Fully on-line models are extremely fast and reliable; therefore, these models need to be rather simple without the need to do any significant numerical calculations. For these models to be reliable, the physics of the process that they are addressing must be understood thoroughly. A good example of this type of model is the spray water system on a slab-casting machine, which is designed to deliver the same total amount of water to each portion of the strand surface. The flow rate changes to account for variations in the casting-speed history experienced by each portion as it passes through the spray zones.

Semi-on-line models are similar to fully on-line models. The distinguishing factor is that rather than the model taking appropriate action, the process engineer analyzes the situation and performs any corrective action, if needed. These models are typically slightly more complex than the fully on-line models because they are essentially run by an operator. These models need to have an excellent user interface and should require minimum user intervention.

Off-line models are typically used in the premanufacturing stage, that is, during research, design, or process parameter determination. These models help to gain an insight into the process itself and thereby help optimize it. There are many general-purpose models as well as models designed to be used for very specific applications. These models are typically very complex and therefore need to be validated thoroughly before being used for any real predictions.

Literature models are those that exist primarily in the literature and are seldom used in conjunction with experiments. Typically these models are developed and run by the same individual. The advantage of literature models is that other developers can benefit from them instead of starting from scratch.

Empirical models are developed through statistical data gathering on a number of similar events. The model does not help one understand the process itself and may not be valid beyond the range of the available data.

Mechanistic models are based on the solution of the mathematical equations that represent the physics of the process that is being addressed. These models are very extensible and study the effect of a variety of external factors on the process.

Neural network models are based on artificial neural networks and provide a range of powerful techniques for solving problems in pattern recognition, data analysis, and control. Neural networks represent a complex, trainable, nonlinear transfer function between inputs and outputs. This allows an effective solution to be found to complex, nonlinear problems such as heat distribution.

Modeling of Manufacturing Processes

Anand J. Paul, Concurrent Technologies Corporation

Important Aspects of Modeling

There are several important issues that need to be addressed to understand what is important in modeling in general and what is important to the current problem in particular. Some of these are briefly discussed below.

Analytical versus Meshed Models. Developing an analytical or a closed-form solution model may be advantageous in many instances. However, it may be necessary to construct a discrete meshed model for finite element or finite difference calculations if the modeled volume:

- Has a complex shape (commonly found in many engineering applications)
- Contains different phases and grains, which are typically modeled by research groups (Ref 4)
- Contains discontinuous behavior such as a phase change, which can be handled easily with meshes using a volume-of-fluid (VOF) technique (Ref 5)
- Has nonlinear process physics such as when the heat transfer coefficient is a nonlinear function of the temperature

In many instances, meshed models are supplemented by some nonmeshed symbolic or analytical modeling. This is done in order to decide on appropriate boundary conditions for the meshed part of the problem because it is the boundary conditions that effectively model the physical problem and control the form of the final solution (Ref 6).

Analytic models are always useful for distinguishing between mechanisms that have to be modeled as a coupled set and mechanisms that can be modeled separately. These models no longer need closed-form solutions. Even simple computers can track evolving solutions and iterate to find solutions to implicit formulations (Ref 1).

Boundary Conditions and Multiphysics Models. Application of appropriate boundary conditions is a major part of the activity of process modeling. Boundary conditions are statements of symmetry, continuity and constancy of temperature, heat flux, strain stress, and so forth. Boundary conditions need to be set at a very early stage in analytical models. In meshed models, these are typically represented separate from the main equations and are decoupled to some extent from the model itself. Therefore, sensitivity analysis can be done much easier using meshed methods.

The type of boundary conditions used also determines what solving algorithm should be used for the partial differential equations. This determines the speed, accuracy, and robustness of the solution.

Material Properties. All process models require material properties to be simulated. Acquiring these properties can be difficult and expensive (Ref 7). A sensitivity analysis of the model with respect to these data provides information as to the importance of minor changes in them. In many instances, it may be possible to use models with doubtful material property information in order to predict trends, as opposed to determining actual values. A problem arises if the material properties are extrapolated beyond the range of their applicability where one does not know the behavior of the material at all. Related information is provided in the articles "Computer-Aided Materials Selection" and "Sources of Materials Properties Data and Information" in this Volume.

Modeling Process Cycles. The process of modeling is done in different cycles. Figure 2 attempts to distinguish those cycles (Ref 8). This figure shows three loops suggesting three levels of activities in any modeling effort. The outer loop is managed by someone close to the process who understands the business context of the problem and can concentrate on specifying the objective and providing the raw data. The innermost loop (shaded dark) requires mostly computational skills while the middle loop (shaded light) consists of activities balancing the other two. It may very well happen that all three of some combination of the activities can be done by the same person. However, very seldom is that the case. This highlights the need for forming modeling teams where all aspects of the problem can be addressed rigorously. It also emphasizes the importance of training and appropriate software tool development so that the input and output of the tools can be easily understood by all involved in the process.

Modeling of Manufacturing Processes

Anand J. Paul, Concurrent Technologies Corporation

Modeling of Deformation Processes

Finite element analysis (FEA) of deformation processes can provide an insight into the behavior of the product under various processing conditions and can help optimize the conditions to get the desired properties. It can also help understand the performance of the product before the part is put in actual use. Common problems solved by FEA include

insufficient die filling, poor shape control, poor flow of material, cracks and voids that lead to fracture and poor final part properties.

The occurrence of typical processes in a forging operation are shown in Fig. 3. Figure 4 (Ref 9) shows a schematic representation of the interactions between the major process variables in metal forming. From Fig. 4 it can be seen that for a metal-forming analysis, one needs to satisfy the equilibrium conditions, compatibility equations/strain-displacement relations, constitutive equations, and, in some instances, the heat balance equation. In addition, one needs to apply appropriate boundary conditions. These may comprise displacement/velocity imposed on a part of the surface while stress is imposed on the remainder of the surface, heat transfer, or any other interface boundary condition.

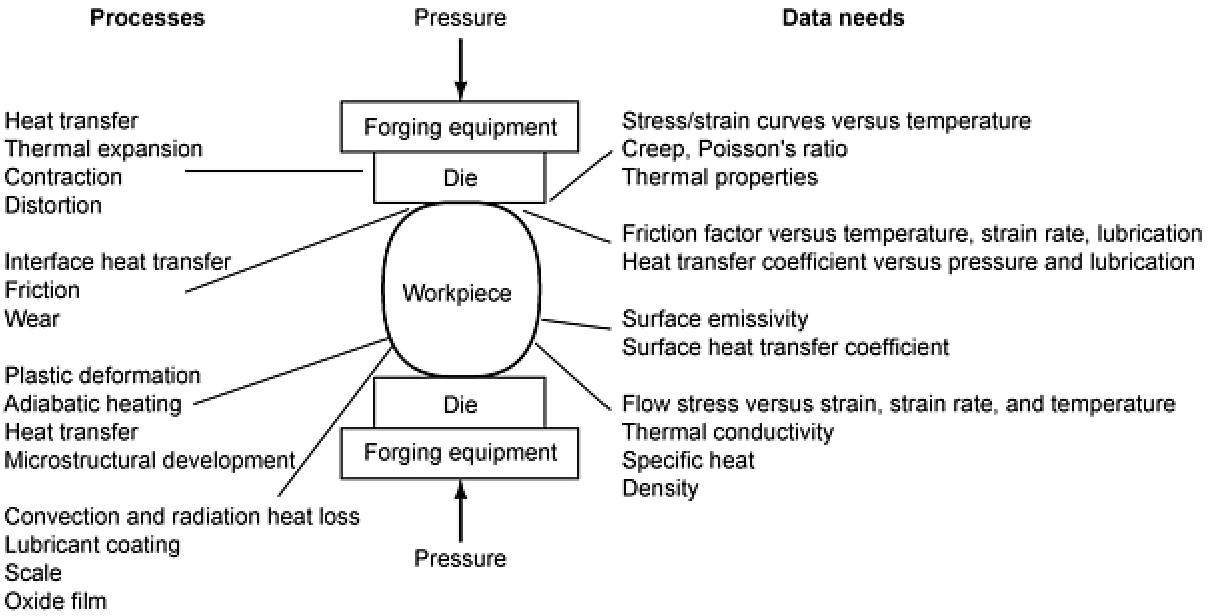

Fig. 3 Typical physical phenomena occurring during a forging operation

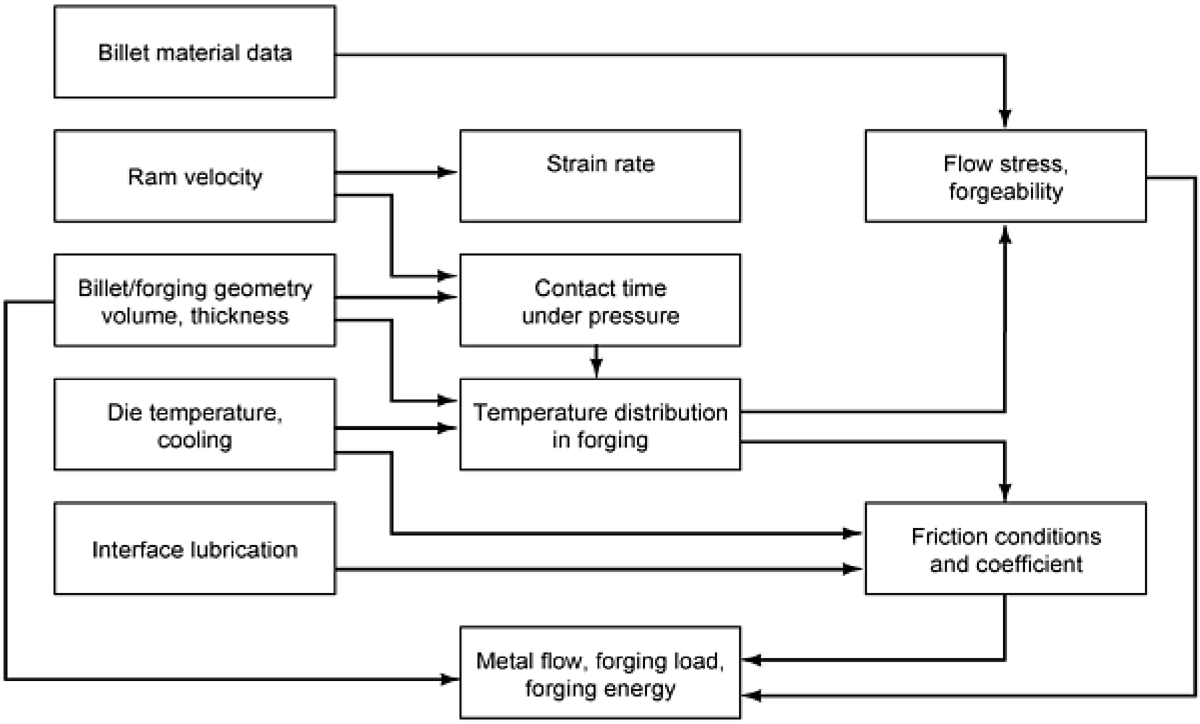

Fig. 4 Interaction among major process variables during forming. Source: Ref 9

Relevant Equations. The equilibrium equations describing the various forces acting on the body are given as:

$$\frac{\partial \sigma_x}{\sigma x} + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z} + F_x = 0$$
$$\frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \sigma_y}{\partial y} + \frac{\partial \tau_{yz}}{\partial z} + F_y = 0 \qquad \textbf{(Eq 1)}$$
$$\frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \frac{\partial \sigma_z}{\partial z} + F_z = 0$$

where σ is the normal stress component, τ is the shear stress component, and *F* is the body force/unit volume component. Similarly, the strain-displacement relationships are given as:

$$\varepsilon_x = \frac{\partial u}{\partial x} \qquad \gamma_{xy} = \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}$$
$$\varepsilon_y = \frac{\partial v}{\partial y} \qquad \gamma_{yz} = \frac{\partial v}{\partial z} + \frac{\partial w}{\partial y} \qquad \textbf{(Eq 2)}$$
$$\varepsilon_z = \frac{\partial w}{\partial z} \qquad \gamma_{zx} = \frac{\partial w}{\partial x} + \frac{\partial u}{\partial z}$$

where ε is the normal strain, γ is the shear strain, and *u*, *v*, and *w* are the displacements in the *x*, *y*, and *z* directions, respectively.

Constitutive Theory. A constitutive equation relates the stress and strain behavior of a material. Schematic stress/strain curves for idealized materials are shown in Fig. 5. In addition to this information, a yield criterion and flow rules are also needed to adequately describe the material behavior. The stress/strain curve for a typical metal along with its major features is shown in Fig. 6.

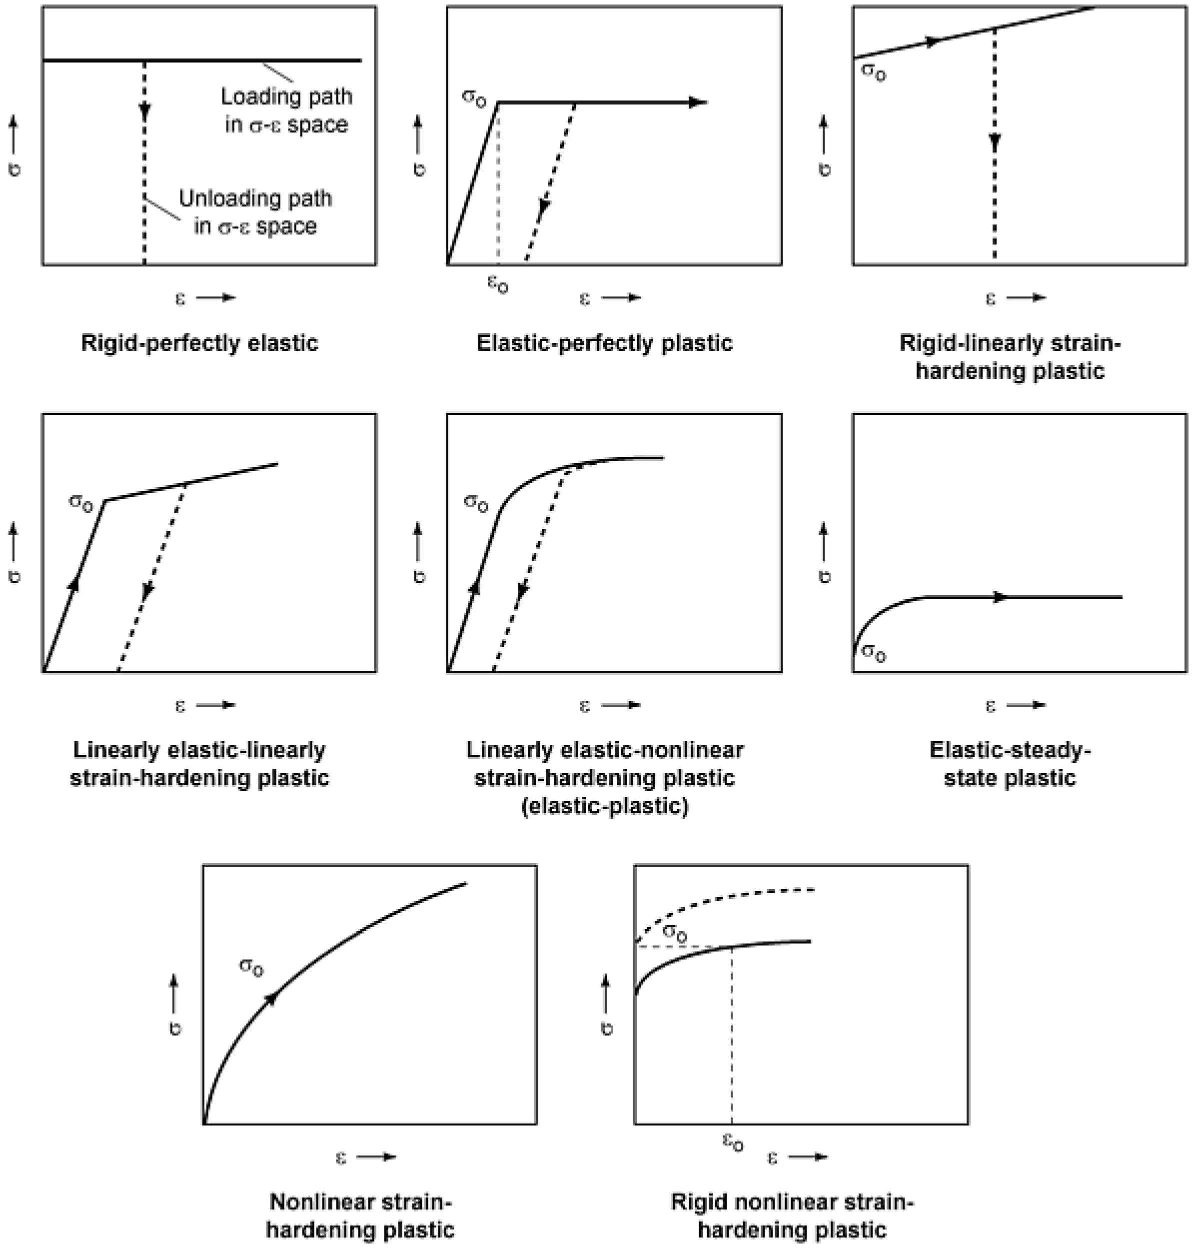

Fig. 5 Schematic stress/strain curves for various materials

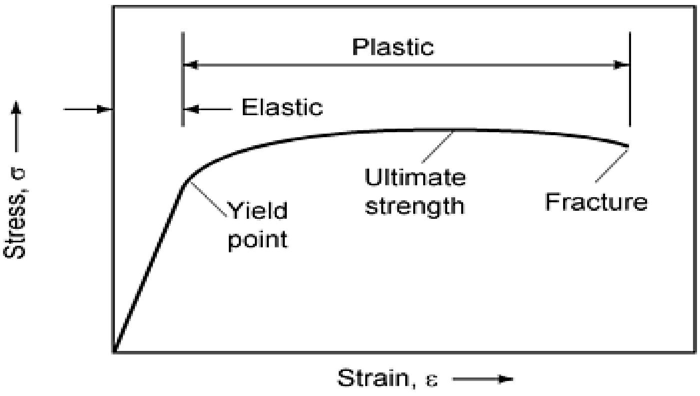

Fig. 6 Stress/strain curve for a typical metal

Finite Element Analyses. One of the most commonly used techniques to solve the various equations (as shown earlier) is finite element analysis (FEA). It is a numerical technique that approximates the mathematical equations that in turn approximate reality. It is a discrete representation of a continuous system. It breaks the bigger problem into a number of smaller ones and, therefore, is a piecewise representation of the problem.

Some of the common metal-forming problems that are solved by FEA are insufficient die fill, poor shape control, poor flow of materials, prediction of cracks and voids that lead to fracture, and poor final part properties. Finite element analysis has many advantages over the typical closed-form solutions. It provides greater insights into the behavior of the product and the process, gives a good understanding of the performance of the product before the actual usage, is useful in product and process optimization, is a powerful and mature design and analysis tool, and most importantly, gives solutions to irregular shapes, variable material properties, and irregular boundary conditions. However, FEA is not to be viewed as a solution to all problems or as a substitute for common sense and experience.

Typical costs of FEA can run into thousands of dollars. A rough estimate is that if brainstorming costs $1, then refined hand calculations would cost $2, "quick and dirty" process models would cost $5, and detailed process models would cost $30. However, the probability of success of detailed process models is much higher compared to that of brainstorming, and great savings in costs of experimentation and rework may be achieved.

There are several steps involved in conducting these analyses. A brief description of each is provided below. More detailed information is provided in the article "Finite Element Analysis" in this Volume.

Defining the Problem. Before a full-fledged FEA is undertaken, several questions need to be answered:

- Is FEA appropriate?
- What is desired from the FEA?
- When are results needed?
- What are the product and process limitations?

If it is determined that FEA would provide adequate answers, information is gathered to start the modeling process. The required information includes the geometry of interest, initial and boundary conditions, material properties and material behavior models, and an approximate solution to ensure that the finite element results are not physically absurd.

The preprocessing stage defines the physical problem and converts it into a form that the computer can solve. The definition of the physical problem involves fully defining the geometry as well as the material of the part to be simulated.

Next comes defining the physics of the process. This involves using the appropriate set of mathematical equations and the corresponding initial conditions and boundary conditions. Subsequently, the solution method needs to be determined. This involves choosing the appropriate algorithms to solve the numerical approximations of the mathematical equations. Finally, because FEA is a numerical approximation of reality, the problem needs to be discretized, (i.e., the continuum needs to be broken into many smaller pieces, the sum of which will represent the whole problem). In this stage, the shape of these smaller pieces, or elements, their size, and their complexity needs to be determined.

Discretization is the process of subdividing the whole geometry into discrete parts. The discrete parts are called elements. Many different types of elements exist depending on their shape, linearity, and order. The factors that impact the selection of the elements are the type of the problem, geometry, accuracy desired, availability within the algorithm, nature of the physical problem, and user familiarity. The size and number of elements are primarily determined by the various gradients (temperature, stress, etc.) in the system. For example, if the gradients are steep, a larger number of smaller-sized elements should be used. An example of discretization is shown in Fig. 7. For clarity, the node and element numbers are not shown in the mesh.

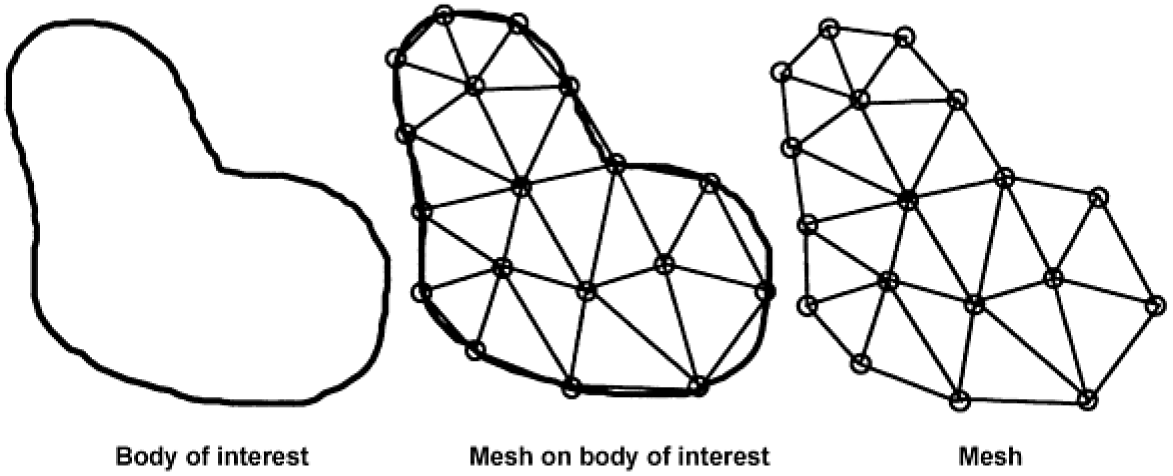

Fig. 7 The finite element analysis discretization process

The mesh can be made coarser (fewer elements) or finer (more elements) depending on the needs of the problem. Coarser meshes use minimal computer resources in terms of storage and run time. However, because the representation is approximate, the results can be crude. Finer meshes provide a more accurate representation with improved results.

Typical elements are either linear or quadratic and can be one-, two- or three-dimensional. Figure 8 schematically shows some typically used elements.

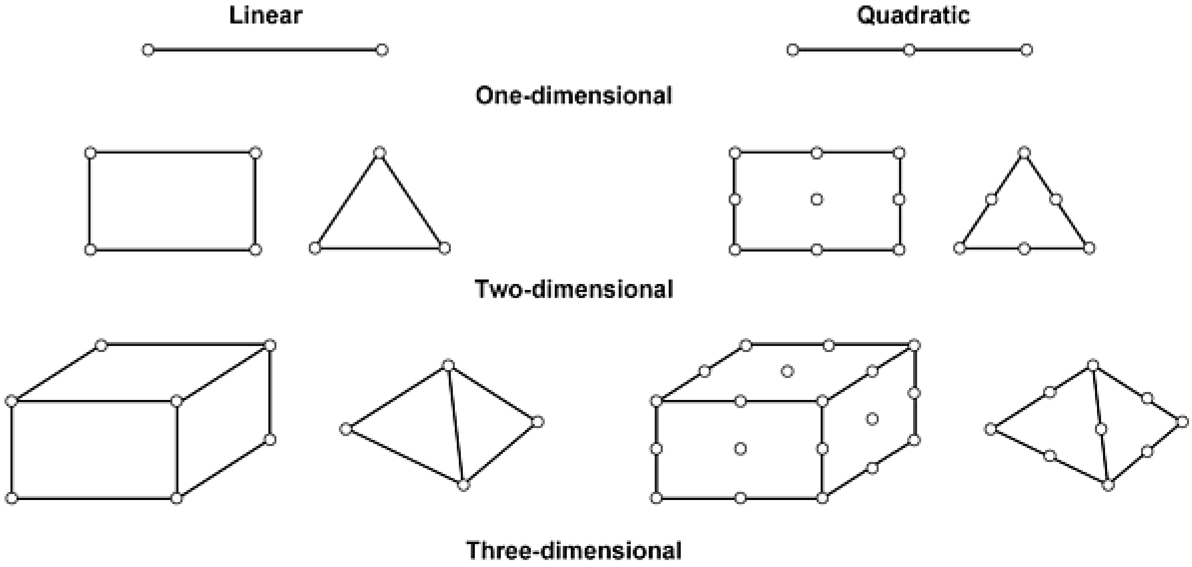

Fig. 8 Linear and quadratic elements used in typical finite element analyses

Post Processing. Once the equations have been solved by the computer program, huge amounts of data are generated that are typically not in a user-friendly format. These data need to be organized and processed so as to make sense and give only the information that the user desires. The most frequently analyzed data are metal flow, time-history plots, ductile fracture tendency, stress/strain plots, and load-stroke curves. A good visualization scheme is crucial to understanding the outcome of the analysis.

Requirements of a Good FEA Code. For an FEA code to be useful, it must be easy to use and provide results that are easy to understand. A well-written user's manual or other documentation and good software support are also

important. From a technical standpoint, the code must also be accurate, fast, and numerically stable under a wide range of conditions. It must be sufficient to capture the physics of the problem and should be capable of being interfaced with other codes (as appropriate).

Example 1: Use of FEA to Study Ductile Fracture during Forging.

Brittle fracture is sometimes observed after forging and heat treating large nickel-copper alloy K-500 (K-Monel) shafts (Ref 10). Inspection of failed fracture surfaces revealed that the cracks were intergranular and occurred along a carbon film that had apparently developed during a slow cooling cycle (such as during casting of the ingot stock). Cracks were observed in both longitudinal and transverse directions and arrested just short of the outer bar diameter. Finite element analysis was used to determine the cause and remedy for this cracking. In addition, new processing parameters were determined to eliminate cracking.

A two-dimensional model of the bar was developed and discretized into a finite element mesh. NIKE2D, a public domain, nonlinear FEA code from Lawrence Livermore National Laboratory (Ref 11), was used to calculate the stress plots under the forging conditions. The stress/strain histories resulting from forging were required for ductile fracture analyses. In this particular case, the Oyane et al. ductile fracture criteria (Ref 12) were used. These criteria attempt to predict ductile fracture based on a porous plasticity model.

Figure 9 (Ref 10) shows in-process hydrostatic stress history at the center of a bar during forging with two rigid, parallel flat dies. (Hydrostatic stress is the mean of any three mutually perpendicular normal stresses at a given point. It is invariant with direction.) Various strain rate and temperature conditions are shown having similar trends. At very low reductions (1.25%), the center of the bar is still within the elastic range and, therefore, does not experience large stresses. At 2.5% reduction, the outward movement of the free sides of the bar produces a high tensile hydrostatic stress at the center of the bar. As reduction continues, the compressive stresses acting in the vertical direction begin to grow. This acts to reduce the hydrostatic stress at the center. When the bar has been reduced by 11%, the hydrostatic stress is compressive in all cases. Beyond this reduction, the hydrostatic stress at the center of the bar continues to grow in a compressive manner.

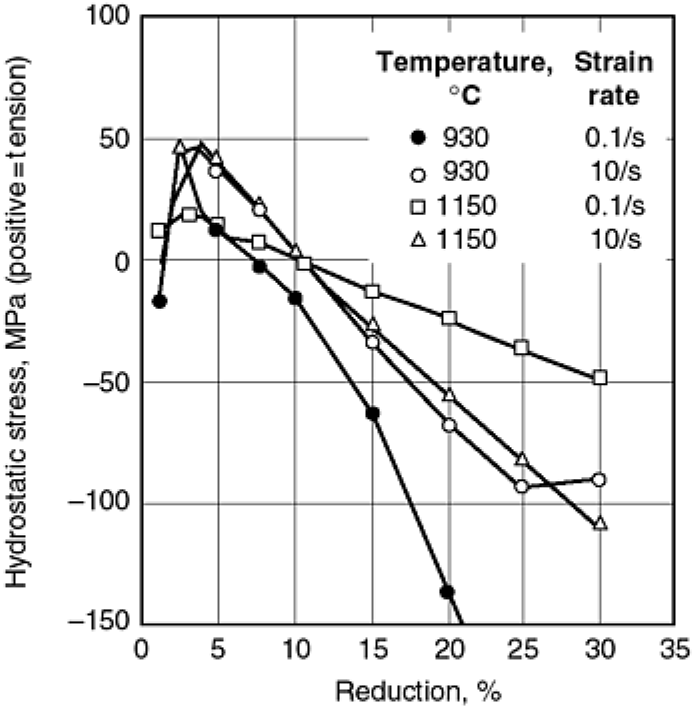

Fig. 9 Hydrostatic stress at the bar center during forging. Source: Ref 10

Figure 10(b) (Ref 10) shows a map of ductile fracture accumulation after one forging pass for air-melted material at 930 °C and a strain rate of 10 s^{-1}. Notice that the maximum damage is located at the center of the bar. After this pass, the bar

would be rotated and further reductions would be taken. Damage would accumulate during these subsequent passes. Ductile fracture was predicted to occur at the bar center from the FEA results after six reducing passes under the specified conditions. One possible way of eliminating this ductile fracture is to use a V-shaped die assembly as shown in Fig. 10(a). In this case, the fracture does not occur at the center, but at the edges and gets an opportunity to heal as the bar is rotated during subsequent passes.

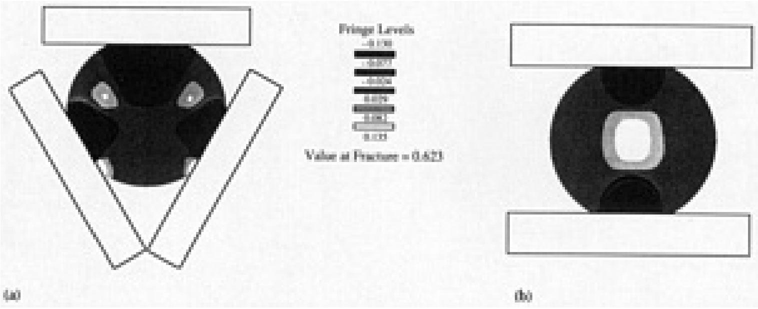

Fig. 10 Ductile fracture map of a nickel-copper alloy K-500 bar at 10% reduction, 930 °C, and a strain rate of 10.0 s^{-1} using the Oyane et al. ductile fracture criteria. (a) Three forging dies. (b) Two forging dies. Source: Ref 10

Example 2: Use of FEA for Modeling Superplastic Forming of Aluminum Assemblies.

Superplastic forming (SPF) technology is being increasingly used for aerospace applications. The major benefits of using SPF include the ability to produce complex near-net shapes better than other forming operations and its good postformed mechanical properties. Even though titanium components have been formed by SPF for some time, SPF of aluminum components pose some challenges. These include the ability of the material to be superplastic only at elevated temperatures and within a small window of strain rates, cavitation, and amount and rate of application of pressure. Superplastic forming of aluminum is usually performed in a closed-die press capable of applying inert gas pressure to both sides of a superplastic sheet. Initially, an equilibrium pressure is applied to both sides of the sheet. Slowly, according to a predesigned forming schedule, pressure is released from one side of the sheet, with the pressure differential pushing the sheet into the die cavity. As the sheet freely forms into the die cavity, thinning occurs relatively uniformly. Once the sheet makes contact with the die, frictional effects begin to make the thinning less uniform.

The constitutive behavior of the superplastic material (aluminum alloy 7475) is expressed in the form of a simple power-law equation:

$$\dot{\varepsilon} = A\,\sigma^n \qquad \textbf{(Eq 3)}$$

where $\dot{\varepsilon}$ is the strain rate, σ is the stress, and A and n (= 1/m) are material constants. The above equation assumes that grain size remains constant during forging. Critical regions, where grain coarsening and an unacceptable amount of cavitation take place, can also be modeling by expressing the material behavior in a more rigorous form:

$$\dot{\varepsilon} = A'\frac{DGb}{kT}\left(\frac{\mathbf{b}}{d}\right)^p\left(\frac{\sigma}{G}\right)^n \exp\left(-\frac{Q}{RT}\right) \qquad \textbf{(Eq 4)}$$

where A' is a material constant, D is the diffusion coefficient, G is the shear modulus, **b** is the Burgers vector, k is the Boltzmann's constant, T is the absolute temperature, d is the grain size, p is the grain size exponent, σ is the flow stress, n is the strain-hardening exponent, Q is the activation energy, and R is the universal gas constant. Cavitation may be expressed as a function of accumulated plastic strain as:

$$C = C_o \exp\,(K_3\bar{\varepsilon}) \qquad \textbf{(Eq 5)}$$

where C_o is the initial void volume, K_3 is a constant, and $\bar{\varepsilon}$ is the accumulated plastic strain.

Several subroutines were developed and implemented in a commercially available FEA code (Ref 13). Several trial forming problems were solved to show the benefits of various enhancements to the FEA code. Simple geometries were first taken to allow comparison of simple analytical solutions with the compared results. Subsequently, complex geometries were discussed to show where the simple analytical solutions broke down and where the FEA results give a significant insight into the forming process.

Modeling of Manufacturing Processes

Anand J. Paul, Concurrent Technologies Corporation

Modeling of Casting Operations

Of late, considerable developments have taken place in the field of solidification modeling of casting processes. In the current state-of-the-art solidification simulation, several software packages are available to analyze the solidification behavior in complex-shaped castings. These packages make use of several different approaches for solving the various problems associated with casting processes.

An overall architecture of a comprehensive solidification modeling system is shown in Fig. 11. This figure (Ref 14) depicts the various modules available in the current state-of-the-art solidification simulation of casting processes, the information available from each module, and the interconnection between the modules. It is evident from the figure that the initial casting design is linked to a module called the quick-analysis module. Here, one can make use of approximate analysis schemes, such as the modulus approach (Ref 15), which uses geometry-based considerations to provide valuable insights into the solidification times and, therefore, the propensity for defect formation during solidification.

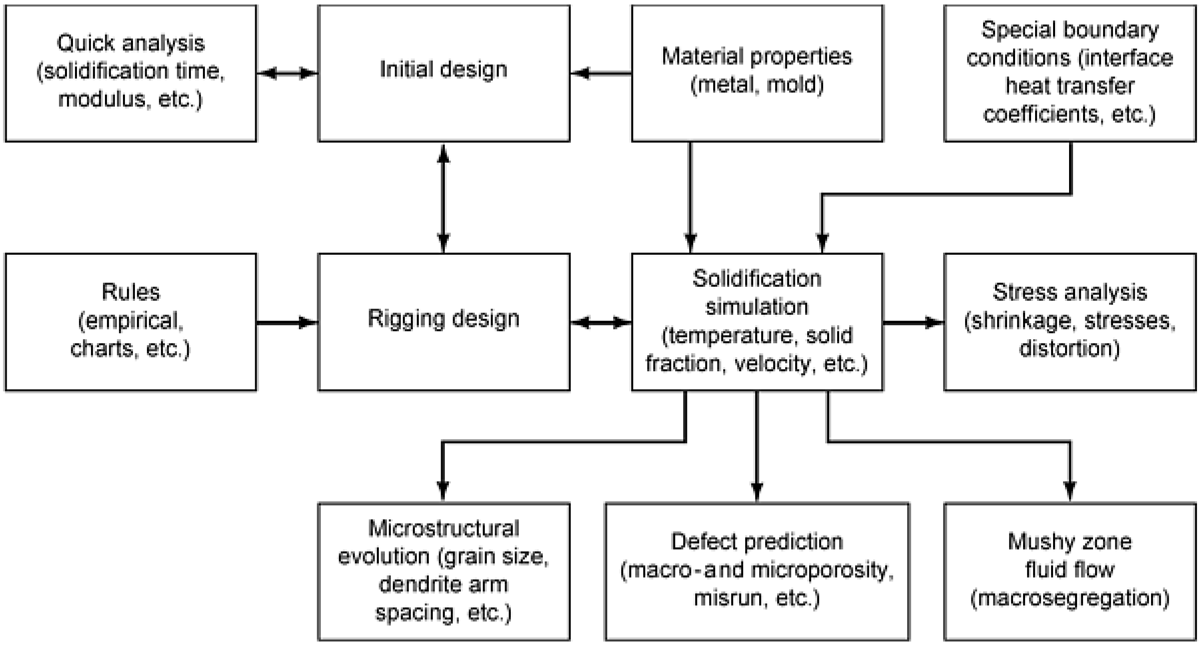

Fig. 11 Overall architecture of the modeling of casting processes. Source: Ref 14

The next stage is to design the rigging system for the casting, which includes the design of the gate, risers, downsprue, and so forth. This is currently based on the "rules of thumb" of foundry experts and empirical charts. Once the rigging design is established, the stage is set for solidification simulation. Here, the continuum mechanics problem of heat, mass, and momentum transfer are solved for the casting process simulation. Thus, one obtains the cooling history of the casting.

Subsequently, one can obtain information about the microstructure in the casting by coupling with the module for microstructure evolution. Further, the simulation data can be postprocessed using special-purpose models for defect prediction that enable one to visualize the defects under a given set of processing conditions. Apart from porosity-type defects, prediction of other defects such as macrosegregation is possible. Because macrosegregation primarily occurs due to the movement of solid phase by convection during solidification, solving the fluid-flow equations in the mushy zone provides a solution.

Modeling the development of stresses in the casting has been another area of great challenge. Of late, several researchers have addressed the issue of development of stresses during and after solidification, which is often the cause of distortion in castings. This is especially the case for highly nonequilibrium processes, such as die-casting. Special numerical algorithms and techniques are being developed for handling more complex casting processes. For example, in large structural thin-walled castings, the normal solution methods would require an extremely large number of elements or nodes in the mesh, which significantly increase the computation time.

Quick-Analysis Schemes. Traditionally, for sand-casting analysis, the use of geometric methods has been known as the section modulus approach. The fundamental basis of geometric modeling is the relationship between the solidification time (t_f) and a geometric parameter, called the section modulus (given by volume-to-surface area ratio, *V*/*A*), as given by Chvorinov's Rule (Ref 16):

$$t_f = C\left(\frac{V}{A}\right)^2 \qquad \textbf{(Eq 6)}$$

where *C* is a constant for a given metal-mold material and mold temperature.

For simple shapes, the modulus in Eq 6 can be calculated from the ratio of volume and surface area involved in cooling. However, for complex shapes discretized in a three-dimensional grid, the continuous distribution of modulus can be

determined using the concept of distance from the mold, as discussed in Ref 15. The modulus at each point in the casting is determined by the relation:

$$M = \frac{2}{\sum_{i=1}^{N} 1/d_i} \quad \text{(Eq 7)}$$

Recently, this technique has been extended to model the investment-casting process, taking radiation loss into account through the use of a novel approach for view-factor calculations (Ref 17).

Knowledge-Based Systems for Rigging Design. The starting step after the initial design of the casting is the design of gates and risers. This consists of proper orientation of the part and the determination of the parting plane and the size, number, and location of sprues, runners, gates, and risers. To this end, the use of knowledge-based design systems is growing for foundry applications. A feature-based design system has been developed for casting applications (Ref 18). Also, a system for design of gating and risering for light alloy castings has been developed (Ref 19). This system was extended to investment castings (Ref 20). In a similar vein, strategies have been developed for shape-feature abstraction in knowledge-based analysis of manufactured components (Ref 21).

However, the drawback of most of the currently available design tools is the lack of a fully integrated system for the design of gates and risers, followed by a comprehensive process simulation. More recently, an attempt has been made to close this gap by developing a system for automatic rigging design (Ref 22). The drawback of this system is that the final design (which includes the part and rigging) is in the form of a finite difference mesh model and not a solid model, which inhibits automatic pattern generation. Currently, efforts are underway to overcome this problem.

In these methods for rigging design, the first step is the generation of the solid model of the part. This solid model is used to generate a discretized description of the part, in the form of a finite difference or finite element mesh. The gating design is achieved by applying some empirical heuristics to the discretized solid model, as well as performing a geometric analysis to determine the natural flow paths for liquid metal. These empirical heuristics include rules for design of runners, sprues, and gates.

As a general rule, the casting should be gated and fed in a manner to ensure progressive solidification of the casting. There should be an adequate supply of molten metal to feed every section as it solidifies. The solidification should start at the location furthest from the ingate/casting junction and proceed toward the risers, which should solidify last. The design of risers involves a geometric analysis of the casting using empirical relations such as Chvorinov's Rule to obtain the solidification time profile, followed by determination of the size and location of the riser. The size of the riser is decided, based on the feed metal requirements as well as the solidification time.

The Comprehensive Problem: Fluid Flow and Heat Transfer. Knowledge about fluid flow during the filling of casting is important, for it affects heat transfer both during and after filling. The information obtained could help avoid problems of cold shuts, where the melt solidifies before filling a void, or where a molten front of liquid comes in contact with a solidified metal. A mold-filling simulation is, therefore, indispensable if a high-quality casting-solidification analysis is desired. There are several computational techniques to simulate fluid flow during mold filling, some of which follow.

Momentum Balance Technique: The Solution Algorithm-Volume of Fluid Approach. To obtain an accurate profile of the velocity distribution in the mold during the filling of castings, one has to solve the governing equations. The main governing equations that need to be solved to track the free surface and obtain the velocity distribution in the melt are the continuity equation, the Navier-Stokes equation, and the equation for free-surface tracking. The continuity equation is given by:

$$\nabla \cdot v = 0 \quad \text{(Eq 8)}$$

where v represents the velocity. The Navier-Stokes equation is:

$$\rho \frac{Dv}{Dt} = \nabla P - \nabla \cdot \tau + \rho g \qquad \text{(Eq 9)}$$

where P is the fluid pressure, τ is the stress tensor, g is the acceleration due to gravity, and ρ is the density. The equation for free-surface tracking is:

$$\frac{\partial}{\partial t}\left(\int_{\Omega} \rho F d\Omega \right) = -\int_{s} \rho F v \cdot n dS \qquad \text{(Eq 10)}$$

where F is a function that defines the fractional volume of the control element occupied by the fluid, Ω is the volume, S is the surface area, and n is the unit normal vector on the surface.

Several boundary conditions are applied to solve the equations, such as no-slip condition at the solid surfaces and atmospheric pressure at the free surface. The solutions to these equations, especially for three-dimensional cases, can be computationally very demanding. Over the past decade, effective algorithms have been developed for simulation of mold filling and solidification using both finite difference as well as finite element methods. Calculation of the location of the liquid and the orientation of its free surface is an integral part of this computational technique.

The thermal history inside the casting and mold is obtained by solving the energy equation:

$$C_P \rho \frac{dT}{dt} = -C_P \rho v \cdot \nabla T - \nabla \cdot q + \dot{Q} \qquad \text{(Eq 11)}$$

where C_P is the specific heat, q is the heat flux, and $\dot{Q}$ is the rate of heat generation.

The boundary conditions can be of three types. In the first type, the temperature at the boundary is specified, and in the second, the heat flux is specified. More popularly, a third type of boundary condition is used, expressing the heat loss at the interface through a heat transfer coefficient:

$$q = -k \frac{dT}{dx}\bigg|_{x = \text{bound}} = h(T - T_0) \qquad \text{(Eq 12)}$$

where h is the effective heat transfer coefficient across the mold-metal interface, T is the casting surface temperature, and T_o is the mold surface temperature.

Recently, an alternative method of solving the volume-of-fluid equation through an analogy between the numerical treatment of filling and solidification has been developed (Ref 23). In this method, an alternative volume-of-fluid equation has been proposed, based on an enthalpy-type variable to determine the function F. Encouraging results have been obtained with this approach.

Modeling Microstructural Evolution. The solution to Eq 11 requires knowledge of the term $\dot{Q}$ (the rate of latent heat evolution during solidification). This term can be described in two ways: specific heat method or latent heat method.

Specific Heat Method. In this classical approach, the latent heat is released by assuming that the solid forms in a specified temperature range. The specified heat is modified as:

$$C_P^* = C_P - \frac{L}{\rho} \frac{df_s}{dT} \qquad \text{(Eq 13)}$$

where L is the latent heat and df_s/dT is the rate of change of solid fraction with temperature, obtained from the phase diagram. Alternatively, one could use the Scheil equation to express solid fraction evolution as:

$$f_s = 1 - \left[\frac{T_f - T}{T_f - T_l}\right]^{1/k-1} \quad \textbf{(Eq 14)}$$

where T_f is the fusion temperature of the pure metal, T_l is the liquidus temperature, and k is the partition coefficient of the alloy. These parameters are obtained from the phase diagram for the alloy. Using the above equation, one can estimate the latent heat released due to the evolution of the primary phase.

The limitation of the above approach is that one cannot obtain information regarding the microstructure, such as grain size. New approaches were developed in the last decade to overcome this limitation (Ref 24, 25). These approaches incorporate the metallurgy of solidification into the simulations. In one such approach, known as the latent heat method, it has been shown that, in order to obtain microstructural information, the evolution of fraction of solid should take into account not only temperature but also the kinetics of nucleation and growth.

Latent Heat Method. In the latent heat method, the term $\dot{Q}$ in Eq 11 is evaluated based on the solidification kinetics of nucleation and growth as applicable to the transformations occurring in the system. The expression for $\dot{Q}$ is given by:

$$\dot{Q} = L \frac{df_s}{dt} \quad \textbf{(Eq 15)}$$

where L is the latent heat of the solidifying phase and is the rate of evolution of fraction of solid. Latent heat generation can be determined through the use of mathematical expressions to describe the evolution of the solid phase. The temperature history in the casting can then be obtained by solving Eq 11. Depending on the nature of the alloy, the expressions can vary. The following section describes the solidification kinetics for equiaxed eutectic structures, which are commonly found in cast iron systems and aluminum-silicon systems.

Probabilistic Models. Useful as they are, the deterministic models suffer from several shortcomings. They neglect any aspect related to crystallographic effects. So they are unable to account for the grain selection near the mold surface, which leads to the columnar region. Furthermore, they do not account for the random nature of equiaxed grains. One cannot visualize the actual evolution of the grains; one can only get an idea of the size of the grains.

To overcome these limitations, several researchers have used an altogether different track to model microstructural evolution (Ref 4, 26). They make use of probabilistic models to simulate the evolution of grain structure. These simulations are more like numerical experiments. In one such work (Ref 26), a Monte Carlo procedure was used to simulate evolution of grain structure. This type of method is based on the principle of minimization of energy, where the energy of a given structural configuration is evaluated considering the present state of the various sites (whether solid or liquid). Transitions are allowed to take place according to randomly generated numbers. Using this technique, the researchers were able to compute two-dimensional microstructures that closely resembled those observed experimentally. The main drawback of such an approach was the lack of a physical basis.

In a more recent investigation (Ref 4), a new approach for modeling grain structure formation during solidification was proposed. Based on a two-dimensional cellular automata technique, the model includes the mechanisms of heterogeneous nucleation and of grain growth. Nucleation occurring at the mold wall, as well as in the liquid metal, is treated by using two distributions of nucleation sites. The location and the crystallographic orientation of the grains are chosen randomly among a large number of cells and a certain number of orientation classes. The model has been applied to small specimens of uniform temperature. The columnar-to-equiaxed transition, the selection and extension of columnar grains that occur in the columnar zone, and the impingement of equiaxed grains are clearly shown by this technique.

Prediction of Defects: The Porosity Problem. Analysis of the conditions leading to the occurrence of casting porosity has been the focus of a number of investigations in the past few decades. With the advances in computer modeling of the casting process in recent years, there has been considerable interest in the usage of numerical heat transfer and solidification models to predict casting porosity.

As far as the solidification parameters are concerned, the variables that control porosity may be narrowed down to the thermal gradient, the rate of solidification, the cooling rate, and the solidification time. Based on these, various approaches have been suggested to predict casting porosity, the oldest being the empirical criteria. Thermal parameters

have also been formulated recently, from Ref 27 and 28. Many of these criteria are based on d'Arcy's Law, approximating the mushy region to a porous medium. The pressure drop in the mushy region is then expressed in terms of thermal criteria functions to predict the onset of porosity.

The current modeling practice is to calculate these criteria functions using the solidification model to predict porosity. Some of these functions are quite successful in predicting porosity in short-freezing-range alloys, though there are many difficulties in applying them for long-freezing-range-alloys. Figure 12 (Ref 14) shows the Niyama distribution for a ductile iron plate casting. The figure clearly shows the defects ending up in the riser, demonstrating adequacy of feeding.

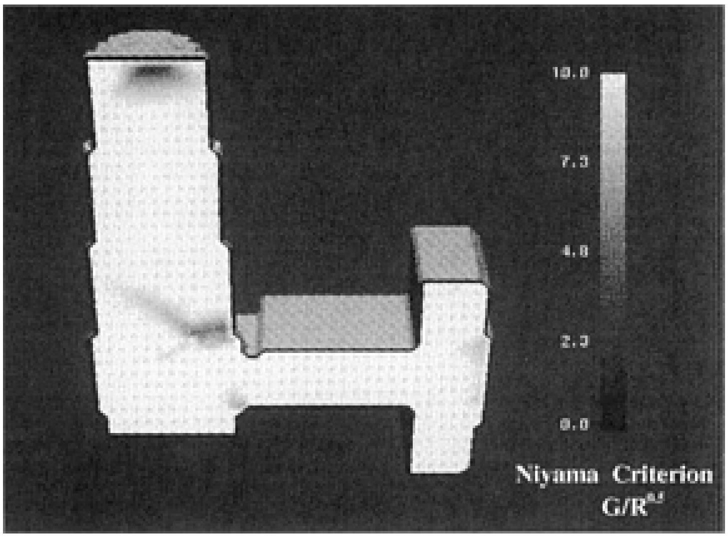

Fig. 12 Distribution of Niyama values in a ductile iron plate casting, showing propensity of defects only in the riser. Source: Ref 14

A major limitation of the criteria functions (discussed previously) to predict porosity is that they ignore the effects of casting macrostructure and grain size on porosity. The resistance to liquid feeding in the mushy region depends on the available surface area of solid in the interdendritic region, which is dictated by the macrostructure and grain size. Recently, Suri et. al. have proposed a new number called the feeding resistance number (Ref 31), which takes into account the effect of casting macrostructure on final porosity. The validity of this proposed criterion to predict porosity is still under investigation.

Modeling Special Casting Processes: The Investment-Casting Process. Many critical and value-added components in automotive, aerospace, and other key industries are manufactured by special casting processes, such as the investment-casting process, lost-foam process, tilt-pour (Cosworth) process, and so forth. Simulation of such processes requires the application of suitable submodels to handle the phenomenological aspects specific to each process. In this section, some of the research efforts in modeling investment casting are reviewed.

A comprehensive solidification simulation of the investment-casting process involves a number of computationally intensive steps, particularly the calculation of view factors (to model the radiation loss), and the three-dimensional analysis of mold-filling and solidification.

The external heat loss is either purely radiative, or radiative as well as convective. For the general case, the heat transfer coefficient can be given by:

$$h = h_r + h_c \quad \textbf{(Eq 16)}$$

where h_r and h_c are the radiative and convective heat transfer coefficients, respectively. The radiative heat transfer coefficient is given by (Ref 32):

$$h_r = \sigma \varepsilon F_{m-a} (T_s^2 + T_o^2)(T_s + T_o) \quad \textbf{(Eq 17)}$$

where σ, ε, and F_{m-a} are the Stefan-Boltzmann constant, the mold emissivity, and the view factor of the mold with respect to air, respectively.

The convective heat transfer coefficient valid for natural convection at high temperature is given by:

$$h_c = c(T_s - T_o)^{1/3} \quad \textbf{(Eq 18)}$$

where *c* is a constant dependent on the surface geometry.

View factor is defined as the fraction of the radiation that leaves surface *i* in all directions and is intercepted by surface *j*. When two surfaces, dA_1 and dA_2 undergo radiation exchange, the view factor can be mathematically expressed as (Ref 32):

$$F_{1-2} = \int_{A_1} \int_{A_2} \frac{\cos \theta \cos \phi}{R_{1-2}^2} dA \quad \textbf{(Eq 19)}$$

were R_{1-2} is the distance between the two surfaces, and $\theta$and $\phi$are the angles of the two surface normals with the line joining the two surfaces.

The calculation of view factors could become very complicated when multiple surfaces are involved in the radiation process. The presence of multiple surfaces can create a partial or full obstruction in the view path between any two surfaces. Thus, the view factors will now depend not only on the two surfaces exchanging heat, but also on the shadows cast by the other surfaces present in the model. Additional calculations are needed for determining the shadowing effects for any realistic three-dimensional geometries.

More recently, another technique has been proposed that enables quick calculation of the view factor distribution at the mold surface (Ref 17). This is a modified ray-racing technique, where a scheme is devised to send rays in various directions, and the number going into air without mold interception is estimated. The view factor is then computed by calculating the fraction of rays that go into air. This scheme has been successfully applied to three-dimensional finite difference geometries.

Modeling of Manufacturing Processes

Anand J. Paul, Concurrent Technologies Corporation

Modeling of Fusion Welding Processes

In fusion welding, parts are joined by melting and subsequent solidification of adjacent areas of two parts. Welding may be performed with or without the addition of a filler metal.

Figure 13 is a schematic diagram of the fusion welding process. Three distinct regions in the weldment are observed: the fusion zone, which undergoes melting and solidification; the heat-affected zone, which experiences significant thermal exposure and may undergo solid-state transformation, but no melting; and the base-metal zone, which is unaffected by the welding process.

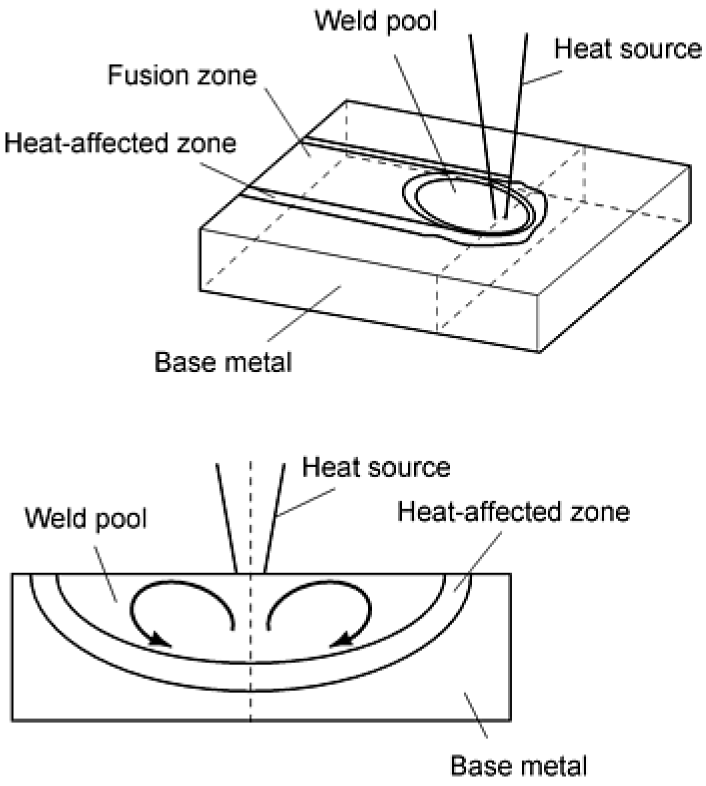

Fig. 13 Schematic representations of the fusion welding process

The interaction of the material and the heat source leads to rapid heating, melting, and vigorous circulation of the molten metal driven by buoyancy, surface tension, impingement or friction, and when electric current is used, electromagnetic forces. The resulting heat transfer and fluid flow affect the size and shape of the weld pool, the cooling rate, and the kinetics and extent of various solid-state transformation reactions in the fusion zone and heat-affected zone. The weld geometry influences dendrite and grain-growth selection processes. Both the partitioning of nitrogen, oxygen, and hydrogen between the weld pool and its surroundings, and the vaporization of alloying elements from the weld-pool surface greatly influence the composition and the resulting microstructure and properties of the weld metal. In many processes, such as the arc welding and laser-beam welding, an electrically conducting, luminous gas plasma forms near the weld pool.

Energy Absorption. During welding, the workpiece absorbs only a portion of the total energy supplied by the heat source. The absorbed energy is responsible for the outcome of the welding process. The consequences of the absorbed energy include formation of the liquid pool, establishment of the time-dependent temperature field in the entire weldment, and the structure and properties of the weldment. Therefore, it is very important to understand the physical processes in the absorption of energy during the welding process. The physical phenomena that influence the energy absorption by the workpiece depends on the nature of the material, the type of heat source, and the parameters of the welding process.

For arc welding, the fraction of the arc energy transferred to the workpiece, η, commonly known as the arc efficiency, is given by (Ref 33):

$$\eta = \frac{q}{VI} = 1 - \frac{q_e + (1-n)q_p + mq_w}{VI} \quad \text{(Eq 20)}$$

where q is the heat absorbed by the workpiece, I and V are the welding current and voltage, respectively, q_e is the heat transferred to the electrode from the heat source, q_p is the energy radiated and convected to the arc column per unit time (of which a proportion n is transferred to the workpiece), and q_w is the heat absorbed by the workpiece (of which a proportion m is radiated away). For a consumable electrode, the amount of energy transferred to the electrode is eventually absorbed by the workpiece. Thus, the above equation is simplified to:

$$\eta = 1 - \frac{(1-n)q_p + mq_w}{VI} \quad \text{(Eq 21)}$$

Fluid Flow in the Weld Pool. The properties of the weld metal are strongly affected by the fluid flow and heat transfer in the weld pool. The flow is driven by surface tension, buoyancy, and, when electric current is used, electromagnetic forces (Ref 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45). In some instances, aerodynamic drag forces of the plasma jet may also contribute to the convection in the weld pool (Ref 46). Buoyancy effects originate from the spatial variation of the liquid-metal density, mainly because of temperature variations and, to a lesser extent, from local composition variations. Electromagnetic effects are a consequence of the interaction between the divergent current path in the weld pool and the magnetic field that it generates. This effect is important in arc and electron-beam welding, especially when a large electric current passes through the weld pool. In arc welding, a high-velocity plasma stream impinges on the weld pool. The friction of the impinging jet on the weld-pool surface can cause significant fluid motion at high currents. Fluid flow and convective heat transfer are often very important in determining the size and shape of the weld pool, the weld macrostructures and microstructures, and the weldability of the material.

Marangoni Force. The spatial gradient of surface tension is a stress, known as the Marangoni stress. The spatial variation of the surface tension at the weld-pool surface can arise owing to variations of both temperature and composition. Frequently, the main driving force for convection is the spatial gradient of surface tension at the weld-pool surface. In most cases, the difference in surface tension is due to the temperature variation at the weld-pool surface. For such a situation, the Marangoni stress can be expressed as:

$$\tau = \frac{d\gamma}{dT}\frac{dT}{dy} \quad \text{(Eq 22)}$$

where τ is the shear stress due to temperature gradient, γ is the interfacial tension, T is the temperature, and y is the distance along the surface from the axis of the heat source. If a boundary layer develops, the shear stress τ can also be expressed as (Ref 47):

$$\tau = \frac{0.332\rho^{1/2}\mu^{1/2}u^{1/2}}{y^{1/2}} \quad \text{(Eq 23)}$$

where ρ is the density, μ is the viscosity, and u is the local velocity.

Buoyancy and Electromagnetic Forces. When the surface-tension gradient is not the main driving force, the maximum velocities can be much smaller. For example, when the flow is buoyancy driven, the maximum velocity, u_m, can be approximated by the following relation (Ref 48):

$$u_m \approx \sqrt{g\beta\Delta T d} \quad \text{(Eq 24)}$$

where g is the acceleration due to gravity, β is the coefficient of volume expansion, ΔT is the temperature difference, and d is the depth. For the values of ΔT = 600 °C, g = 981 cm/s^2, β = 3.5 × 10^{-5}/°C, and d = 0.5 cm, the value of u_m is 3.2 cm/s. The existence of electromagnetically driven flow was demonstrated by Woods and Milner (Ref 49), who observed flow of liquid metal when current was passed in the metal bath by means of a graphite electrode. In the case of electromagnetically driven flow in the weld pool, the velocity values reported in the literature are typically in the range of 2 to 20 cm/s (Ref 50). The magnitude of the velocities of both buoyancy and electromagnetically driven flows in the weld pool are commonly much smaller than those obtained for surface-tension-driven flows.

Convection Effects on Weld-Pool Shape and Size. Variable depth of penetration during the welding of different batches of a commercial material with composition within a prescribed range has received considerable attention. Often, the penetration depth is strongly influenced by the concentration of surface-active elements such as oxygen or sulfur in steels. These surface-active impurity elements can affect the temperature coefficient of surface tension, $d\gamma/dT$, the resulting direction of convective flow in the weld pool (Ref 51), and the shape of the weld pool. The interfacial tension in

these systems could be described by a formalism based on the combination of Gibbs and Langmuir absorption isotherms (Ref 52):

$$\gamma = \gamma_m^o - A(T - T_m) - RT\,\Gamma_s \ln\left(1 + k_1 a_i e^{-\Delta H^o / R'T}\right) \qquad \textbf{(Eq 25)}$$

where γ is the interfacial tension as a function of composition and temperature, γ_m^o is the interfacial tension of the pure metal at the melting point T_m, A is the temperature coefficient of surface tension for the pure metal, R and R' are the gas constants in appropriate units, T is the absolute temperature, Γ_s is the surface excess of the solute at saturation solubility, k_1 is the entropy factor, a_i is the activity of the solute, and ΔH^o is the enthalpy of segregation. The calculated values (Ref 53) of surface tension for Fe-O alloys are shown in Fig. 14. It is seen that for certain concentrations of oxygen, $d\gamma/dT$ can change from a positive value at "low" temperature to a negative value at "high" temperature. This implies that in a weld pool containing fairly high oxygen contents, $d\gamma/dT$ can go through an inflection point on the surface of the pool. Under these conditions, the fluid flow in the weld pool is more complicated than a simple recirculation.

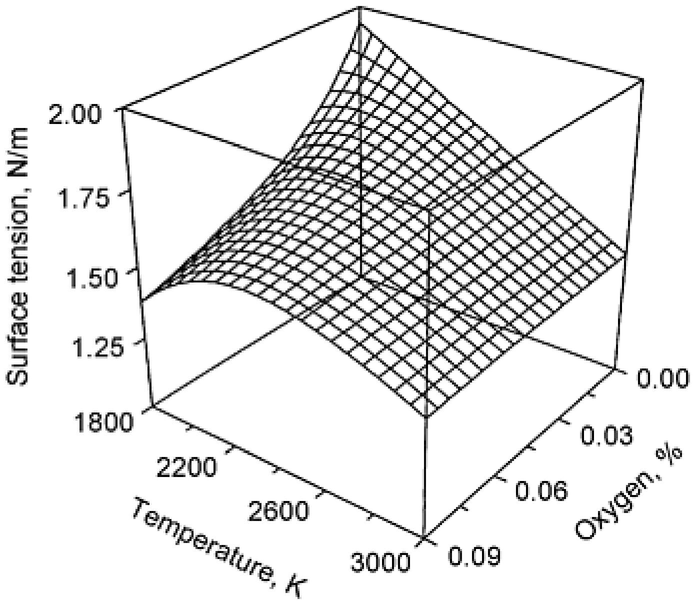

Fig. 14 Calculated values of surface tension for Fe-O alloys. Source: Ref 53

The calculated gas tungsten arc weld (GTAW) fusion-zone profiles (Ref 53) for pure iron, and an Fe-0.03O alloy are shown in Fig. 15. The results clearly show the significant effect of oxygen concentration on the weld-pool shape and the aspect ratio. Near the heat source, where the temperature is very high, the flow is radially outward. However, a short distance away from the heat source, where the temperature drops below the threshold value for the change in the sign of $d\gamma/dT$, the flow reverses in direction. The flow field is not a simple recirculation. Although the qualitative effects of the role of surface-active elements are known, the numerical calculations provide a basis for quantitative assessment of their role in the development of weld-pool geometry.

Modeling of Manufacturing Processes

Anand J. Paul, Concurrent Technologies Corporation

Conclusions

Much work has been done in developing techniques to simulate various manufacturing processes. These efforts range from conducting basic materials research to advanced software engineering. Through an optimum combination of these, tools can be developed that reduce manufacturing costs and increase quality. In fact, many such commercial tools are available today and are being utilized in the manufacturing operations of many companies. However, for modeling to have a significant impact on the manufacturing industry, it should be geared toward the small- and medium-sized enterprises that make up the bulk of the industry. Issues such as personnel training, well-integrated software environments, and help in setting up problems are important. Today, software developers and vendors are working to address these issues in an effort to enable users to take full advantage of the benefits that modeling and simulation can provide to the manufacturing industry.

Manufacturing Cost Estimating

David P. Hoult and C. Lawrence Meador, Massachusetts Institute of Technology

Introduction

COST ESTIMATION is an essential part in the design, development, and use of products. In the development and design of a manufactured product, phases include concept assessment, demonstrations of key features, and detailed design and production. The next phase is the operation and maintenance of the product, and finally, its disposal. Cost estimation arises in each of these phases, but the cost impacts are greater in the development and design phases.

Anecdotes, experience, and some data (Ref 1, 2) support the common observation that by the time 20% of a product is specified, 70 to 80% of the costs are committed, even if those costs are unknown! Another common perception is that the cost of correcting a design error (cost overrun) rises very steeply as product development proceeds through its phases. What might cost one unit of effort to fix in the concept assessment phase might cost a thousand units in detailed engineering. These experiences of engineers and designers force the cost estimator to think carefully about the context, timing, and use of cost estimates.

Manufacturing Cost Estimating

David P. Hoult and C. Lawrence Meador, Massachusetts Institute of Technology

General Concepts

In this article, the focus is on products defined by dimensions and tolerances, made from solid materials and, fabricated by some manufacturing process. Two issues should be apparent: first, accurate cost estimates of a product in its early stages of design is difficult; second, there are a very large number of manufacturing processes, so one must somehow restrict the discussion to achieve sensible results.

In dealing with the first issue a series of cost estimates corresponding to the phases in the product-development program should be considered. As more details of the product are specified, the cost estimates should become more accurate. Thinking this way, it is plausible that different tools for cost estimation may be employed in different phases of a program. In this review examples are given of methods of cost estimation that may be used in the contexts of the different phases of a development program.

Domain Limitation. The second issue gives rise to the important principle of *domain limitations* (Ref 3, 4), meaning data that form the basis for a cost estimate must be specific to the manufacturing process, the materials used, and so on. Cost estimates only apply within specific domains. This leads directly to another difficulty: most products, even if they are only moderately complex, like a dishwasher with 200 unique parts, have a least three or five domains in which cost estimates apply (i.e., sheet metal assembly, injection-molded plastic parts, formed sheet metal parts, etc.). More complex products, such as an aircraft jet engine with 25,000 unique parts, might have 200 different manufacturing processes, each of which defines one or more domains of cost estimation. Clearly, as one considers still more complex products, such as a modern military radar system with 10,000 to 20,000 unique parts, or a large commercial airliner with perhaps 5 million

unique parts, the domains of cost estimation expand dramatically. So, although domain limitation is necessary for cost-estimates accuracy, it is not a panacea.

Database Commonality. Estimating the costs of a complex product through various phases of development and production requires organization of large amounts of data. If the data for design, manufacturing, and cost are linked, there is *database commonality.* It has been found (Ref 3) that having database commonality results in dramatic reductions in cost and schedule overruns in military programs. In the same study, domain limitation was found to be essential in achieving database commonality.

Having database commonality with domain limitation implies that the links between the design and specific manufacturing processes, with their associated costs, are understood and delineated. Focusing on specific manufacturing processes allows one to collect and organize data on where and how costs arise in specific processes. With this focus, the accuracy of cost estimates can be determined, provided that uniform methods of estimation are used, and provided that, over time, the cost estimates are compared with the actual costs as they arise in production. In this manner, the accuracy of complex cost estimates may be established and improved.

In present engineering and design practice, many organizations do not have adequate database commonality, and the accuracy of cost estimates is not well known. Database commonality requires an enterprise-wide description of cost-dominant manufacturing processes, a way of tracking actual costs for each part, and a way of giving this information--in an appropriate format--to designers and cost estimators. Most "empirical methods" of cost estimation, which are based on industrywide studies of statistical correlation of cost, may or may not apply to the experience of a specific firm (see the discussion in the sections that follow).

Costs are "rolled up" for a product when all elements of the cost of a product are accounted for. Criteria for cost estimation using database commonality is simple: speed (how long does it take to roll up a cost estimate on a new design), accuracy (what is the standard deviation of the estimate, based on comparison with actual costs) and risk (what is the probability distribution of the cost estimate; what fraction of the time will the estimate be more than 30% too low, for example). One excellent indicator of database commonality is the roll-up time criteria. World-class cost-estimation roll-up times are minutes to fractions of days. Organizations that have such rapid roll-up times have significantly less cost and schedule overruns on military projects (Ref 3).

Cost allocation is another general issue. Cost allocation refers to the process by which the components of a design are assigned target costs. The need for cost allocation is clear: how else would an engineer, working on a large project, know how much the part being designed should cost? And, if the cost is unknown and the target cost is not met, there will be time delays, and hence costs incurred due to unnecessary design iteration. It is generally recognized that having integrated product teams (IPTs) is a good industrial practice. Integrated product teams should allocate costs at the earliest stages of a development program. Cost estimates should be performed concurrently with the design effort throughout the development process. Clearly, estimating costs at early stages in a development program, for example, when the concept of the product is being assessed, requires quite different tools than when most or all the details of the design are specified. Various tools that can be used to estimate cost at different stages of the development process are described later in this section.

Elements of Cost. There are many elements of cost. The simplest to understand is the cost of material. For example, if a part is made of aluminum and is fabricated from 10 lb of the material, if the grade of aluminum costs $2/lb, the material cost is $20. The estimate gets only a bit more complex if, as in the case of some aerospace components, some 90% of the materials will be machined away; then the sale on scrap material is deducted from the material cost.

Tooling and fixtures are the next easiest items to understand. If tools are used for only one product, and the lifetime of the tool is known or can be estimated, then only the design and fabrication cost of the tool is needed. Estimates of the fabrication costs for tooling are of the same form as those for the fabricated parts. The design cost estimate raises a difficult and general problem: cost capture (Ref 4). For example, tooling design costs are often classified as overhead, even though the cost of tools relates to design features. In many accounting systems, manufacturing costs are assigned "standard values," and variances from the standard values are tabulated. This accounting methodology does not, in general, allow the cost engineer to determine the actual costs of various design features of a part. In the ledger entries of many accounting systems, there is no allocation of costs to specific activities or no activity-based accounting (ABC) (Ref 5). In such cases there are no data to support design cost estimates.

Direct labor for products or parts that have a high yield in manufacturing normally have straightforward cost estimates, based on statistical correlation to direct labor for past parts of a similar kind. However, for parts that have a large amount of rework the consideration is more complex, and the issues of cost capture and the lack of ABC arise again. Rework may be an indication of uncontrolled variation of the manufacturing process. The problem is that rework and its supervision may be classified all, or in part, as manufacturing overhead. For these reasons, the true cost of rework may not be well known, and so the data to support cost estimates for rework may be lacking.

The cost estimates of those parts of overheads that are associated with the design and production of a product are particularly difficult to estimate, due to the lack of ABC and the problem of cost capture. For products built in large volumes, of simple or moderate complexity, cost estimates of overheads are commonly done in the simplest possible way: the duration of the project and the level of effort are used to estimate the overhead. This practice does not lead to major errors because the overhead is a small fraction of the unit cost of the product.

For highly engineered, complex products built in low volume, cost estimation is very difficult. In such cases the problem of cost capture is also very serious (Ref 4).

Machining costs are normally related to the machine time required and a capital asset model for the machine, including depreciation, training, and maintenance. With a capital asset model, the focus of the cost estimate is the time to manufacture. A similar discussion holds for assembly costs: with a suitable capital asset model, the focus of the cost estimate is the time to assemble the product (Ref 1).

Methods of Cost Estimations. There are three methods of cost estimation discussed in the following sections of this article. The first is parametric cost estimation. Starting from the simplest description of the product, an estimate of its overall cost is developed. One might think that such estimates would be hopelessly inaccurate because so little is specified about the product, but this is not the case. The key to this method is a careful limitation of the *domain* of the estimate (see the previous section). This example deals with the estimate of the weight of an aircraft. The cost of the aircraft would then be calculated using dollars/pound typical of the aircraft type. Parametric cost estimation is the generally accepted method of cost estimation in the concept assessment phases of a development program. The accuracy is surprisingly good--about 30% (provided that recent product-design evolution has not been extensive).

The second method of cost estimation is empirically based: one identifies specific design features and then uses statistical correlation of costs of past designs to estimate the cost of the new design. This empirical method is by far the most common in use. For the empirical method to work well, the features of the product for which the estimate is made should be unambiguously related to features of prior designs, and the costs of prior designs unambiguously related to design features. Common practice is to account for only the major features of a design and to ignore details. Empirical methods are very useful in generating a rough ranking of the costs of different designs and are commonly used for that purpose (Ref 1, 6, 7). However, there are deficiencies inherent in the empirical methods commonly used.

The mapping of design features to manufacturing processes to costs is not one-to-one. Rather, the same design feature may be made in many different ways. This difficulty, the feature mapping problem, discussed in Ref 4, limits the accuracy of empirical methods and makes the assessment of risk very difficult. The problem is implicit in all empirical methods. The problem is that the data upon which the cost correlation is based may assume the use of manufacturing methods to generate the features of the design that do not apply to the new design. It is extraordinarily difficult to determine the implicit assumptions made about manufacturing processes used in a prior empirical correlation. A commonly stated accuracy goal of empirical cost estimates is 15 to 25%, but there is very little data published on the actual accuracy of the cost estimate when it is applied to new data.

The final method discussed in this article is based on the recent development called complexity theory. A mathematically rigorous definition of complexity in design has been formulated (Ref 8). In brief, complexity theory offers some improvement over traditional empirical methods: there is a rational way to assess the risk in a design, and there are ways of making the feature mapping explicit rather than implicit. Perhaps the most significant improvement is the capability to capture the cost impact of essentially all the design detail in a cost estimate. This allows designers and cost estimators to explore, in a new way, methods to achieve cost savings in complex parts and assemblies.

Manufacturing Cost Estimating

David P. Hoult and C. Lawrence Meador, Massachusetts Institute of Technology

---

Parametric Methods

An example for illustrating parametric cost estimation is that of aircraft. In Ref 9, Roskam--a widely recognized researcher in this field--describes a method to determine the size (weight) of an aircraft. Such a calculation is typical of parametric methods. To determine cost from weight, one would typically correlate costs (inflation adjusted) of past aircraft of similar complexity with their weight. Thus weight is surrogate for cost for a given level of complexity.

Most parametric methods are based on such surrogates. For another simple example, consider that large coal-fired power plants, based on a steam cycle, cost about $1500/kW to be built. So, if the year the plant is to be built (for inflation adjustment) and its kW output is known, parametric cost estimate can be readily obtained.

Parametric cost estimates have the advantage that little needs to be known about the product to produce the estimate. Thus, parametric methods are often the only ones available in the initial (concept assessment) stages of product development.

The first step in a parametric cost estimation is to limit the domain of application. Roskam correlates statistical data for a dozen types of aircraft and fifteen sub types. The example he uses to explain the method is that of a twin-engine, propeller-driven airplane. The mission profile of this machine is given in Fig. 1 (Ref 9).

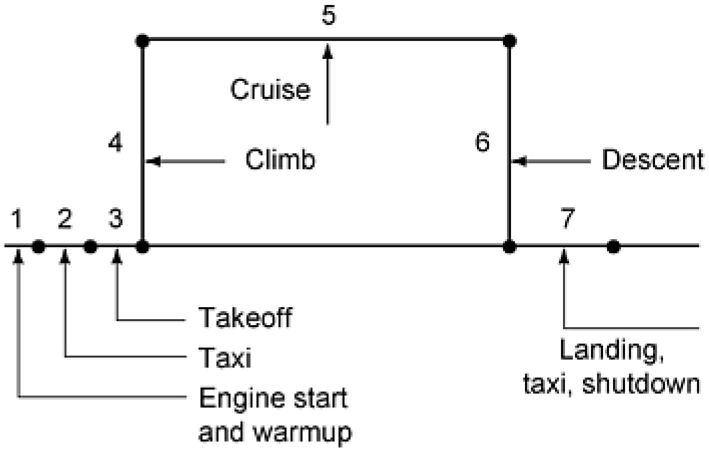

Fig. 1 Mission profile

Inspection of the mission specifications and Fig. 1 shows that only a modest amount of information about the airplane is given. In particular, nothing is specified about the detailed design of the machine! The task is to estimate the total weight, W_{TO} or the empty weight, W_E, of the airplane. Roskam argues that the total weight is equal to the sum of the empty weight, fuel weight, W_F, payload and crew weight, $W_{PL} + W_{crew}$, and the trapped fuel and oil, which is modeled as a fraction, M_{tfo}, to the total weight. M_{tfo} is to be a small (constant) number, typically 0.001 to 0.005. Thus the fundamental equation for aircraft weight is:

$$W_{TO} = W_E + W_F + W_{PL} + W_{crew} + M_{tfo}W_{TO} \qquad \textbf{(Eq 1)}$$

The basic idea of Roskam is that there is an empirical relationship between aircraft empty and total weights, which he finds to be:

$$\log_{10}W_E = \{(\log_{10}W_{TO}) - A\}/B \qquad \textbf{(Eq 2)}$$

The coefficients, A and B, depend on which of the dozen types and fifteen subtypes of aircraft fit the description in Table 1 and Fig. 1. It is at this point that the principle of domain limitation first enters. For the example used by Roskam, the correlation used to determine $A = 0.0966$ and $B = 1.0298$ for the twin-engine, propeller-driven aircraft spans a range of empty weights from 1000 to 7000 lb.

Table 1 Mission specification for a twin-engine, propeller-driven airplane

1. Payload	**Six passengers at 175 lb each (including the pilot) and 200 lb total baggage**
2. Range	1000 statute miles with maximum payload
3. Reserves	25% of mission fuel
4. Cruise speed	250 knots at 75% power at 10,000 ft and at takeoff weight
5. Climb	10 min to 10,000 ft at takeoff weight
6. Takeoff and landing	1500 ft ground fun at sea level, standard day. Landing at 0.95 of takeoff weight
7. Powerplants	Piston/propeller
8. Certification base	FAR23

The method proceeds as follows to determine the weight of fuel required in the following way. The mission fuel, W_F, can be broken down into the weight of the fuel used and the reserve fuel:

$$W_F = W_{Fres} + W_{Fused} \qquad \textbf{(Eq 3)}$$

Roskam models the reserve fuel as a fraction of the fuel used (see Table 1). The fuel used is modeled as a fraction of the total weight, and depends on the phase of the mission, as described in Fig. 1. For mission phases that are not fuel intensive, a fixed ratio of the weight at the end of the phase to that at the beginning of the phase is given. Again, these ratios are specific to the type of aircraft. For fuel-intensive phases, in this example the cruise phase, there is a relationship between the lift/drag ratio of the aircraft, the engine fuel efficiency, and the propeller efficiency. Again, these three parameters are specific to the type of aircraft.

When the fuel fraction of the total weight is determined by either a cruise calculation, or by the ratio of weight at the end of a mission phase to the beginning of a mission phase, the empty weight can be written in terms of the total weight. Then Eq 2 is used to find the total weight of the aircraft.

For the problem posed, Roskam obtains an estimated total weight of 7900 lb. The accuracy can be estimated from the scatter in the correlation used to determine the coefficients A and B, and is about 30%. For details of the method Roskam uses for obtaining the solution, refer to Ref 9.

Some limitations of the parametric estimating method are of general interest. For example, if the proposed aircraft does not fit any of the domains of the estimating model, the approach is of little use. Such an example might be the V-22, a tilt wing aircraft (Ref 10), which flies like a fixed-wing machine, but tilts its wings and propellers, allowing the craft to hover like a helicopter during take-off and landing. Such a machine might be considered outside the domain of Roskam's estimating model. The point is not that the model is inadequate (the V-22 is more recent than Roskam's 1986 article), but the limited product knowledge in the early stages of development makes it difficult to determine if a cost estimate for the V-22 fits in a well-established domain.

Conversely, even complex machines, such as aircraft, are amenable to parametric cost estimates with fairly good accuracy, provided they are within the domain of the cost model. In the same article, Roskam presents data for transport jets, such as those used by airlines. It should be emphasized that the weight (and hence cost) of such machines, with more than one million unique parts, can be roughly estimated by parametric methods.

Of course, cost is not the same as weight or, for that matter, any other engineering parameter. The details of the manufacturing process, inventory control, design change management, and so forth, all play a role in the relationship between weight and cost. The more complex the machine, the more difficult it is to understand if the domain of the parametric cost-estimating model is the same as that of the product being estimated.

Manufacturing Cost Estimating

David P. Hoult and C. Lawrence Meador, Massachusetts Institute of Technology

Empirical Methods of Cost Estimation

Almost all the cost-estimating methods published in the literature are based on correlation of some feature or property of the part to be manufactured. Two examples are presented. The first is from the book by Boothroyd, Dewhurst, and Knight (Ref 1), hereafter referred to as BDK. Chapter 9 of this book is devoted to "Design for Sheet Metalworking." The first part of this chapter is devoted to estimates of the costs of the dies used for sheet metal fabrication. This example was chosen because the work of these authors is well recognized. (Boothroyd and Dewhurst Inc. sells widely used software for design for manufacture and design assembly.) In this chapter of the book, the concept of "complexity" of stamped sheet metal parts arises. The complexity of mechanical parts is discussed in the section "Complexity Theory" in this article.

Example 1: Cost Estimates for Sheet Metal Parts.

Sheet metal comes in some 15 standard gages, ranging in thickness from 0.38 to 5.08 mm. It is commonly available in steel, aluminum, copper, and titanium. Typical prices for these materials are 0.80-0.90$/lb for low-carbon steel, $6.00-$7.00/lb for stainless steel, $3.00/lb for aluminum, $10.00/lb for copper, and $20.00/lb for titanium. It is typically shipped in large coils or large sheets.

Automobiles and appliances use large amounts of steel sheet metal. Aluminum sheet metal is used in commercial aircraft manufacture, but in lesser amounts due to the smaller number of units produced.

Sheet metal is fabricated by shearing and forming operations, carried out by dies mounted in presses. Presses have beds, which range in size from 50 by 30 cm to 210 by 140 cm (20 by 12 in. to 82 by 55 in.). The press force ranges from 200 to 4500 kN (45 to 1000 lbf). The speed ranges from 100 strokes/min to 15 strokes/min in larger sizes.

Dies typically have four components: a basic die set; a punch, held by the die set, which shears or forms the metal; a die plate through which or on which the punch acts; and a stripper plate, which removes the scrap at the end of the fabrication process.

BDK estimate the basic die set cost (C_{ds}, in U.S. dollars) as basically scaling with usable area (A_u, in cm^2):

$$C_{ds} = 120 + 0.36A_u \qquad \textbf{(Eq 4)}$$

The coefficients (Eq 4) arise from correlating about 50 data points of die set cost with useable area. The tooling elements (the punch, die plate, and stripper plate) are estimated with a point system as follows: let the complexity of the part to be fabricated be X_p. Suppose that the profile has a perimeter P (cm), and that the part has an over width and length of W (cm) and L (cm) of the smallest dimensions which surround the punch. The complexity of the part is taken to be:

$$X_p = (P/L)(P/W) \qquad \textbf{(Eq 5)}$$

The assessment of how part complexity affects cost arises repeatedly in cost estimating. The subject is discussed at length in the next section "Complexity Theory" . From the data of BDK, the basic time to manufacture the die set (M, in hours) can be estimated by the following steps: Define the basic manufacturing points (M_{po}) as

$$M_{po} = 30 + 0.56X_p^{2/3} \qquad \textbf{(Eq 6)}$$

Note that the manufacturing time increases a bit less than linearly with part complexity. This is consistent with the section "Complexity Theory" . BDK goes on to add two correction factors to M_{po}. The first is a correction factor due to plate size and part complexity, f_{LW}. From BDK data it is found:

$$f_{LW} = 1 + 0.0276LWX_p^{0.093} \qquad \textbf{(Eq 7)}$$

The second correction factor is to account for the die plate thickness. BDK cites Nordquist (Ref 11), who gives a recommended die thickness, h_d, as:

$$h_d = 9 + 2.5 \log_e(U/U_{ms})Vh^2 \qquad \textbf{(Eq 8)}$$

where U is the ultimate tensile stress of the sheet metal, U_{ms} is the ultimate stress of mild steel, a reference value, V, is the required production volume, and h is the thickness (in mm) of the metal to be stamped. BDK recommends the second correction factor to be:

$$f_d = 0.5 + 0.02h_d \text{ or } f_d = 0.75 \qquad \textbf{(Eq 9)}$$

whichever is greater.

The corrected labor hours, M_p, are then estimated as:

$$M_p = f_d f_{LW} M_{po} \qquad \textbf{(Eq 10)}$$

The cost of the die is the sum of the corrected labor hours times the labor rate of the die fabricator plus the basic die set cost, from Eq 4.

As a typical example of the empirical cost estimating methods, the BDK method takes into account several factors such as the production volume, the strength of the material (relating to how durable the die needs to be), the die size, and complexity of the part. These factors clearly influence die cost. However, the specific form of the equations are chosen as convenient representations of the data at hand. (As, indeed, are Eq 6 and 7, derived by fitting BDK data.)

The die cost risk (i.e., uncertainty of the resulting estimate of die cost) is unknown, because it is not known how the model equations would change with different manufacturing processes or different die design methods.

It is worth noting carefully that only some features of the design of the part enter the cost estimate: the length and width of the punch area, the perimeter of the part to be made, the material, and the production volume. Thus, the product and die designers do not need to be complete in all details to make a cost estimate. Hence, the estimate can be made earlier in the product-development process. Cost trades between different designs can be made at an early stage in the product-development cycle with empirical methods.

Example 2: Assembly Estimate for Riveted Parts.

The American Machinist Cost Estimator (Ref 7) is a very widely used tool for empirical cost estimation. It contains data on 126 different manufacturing processes. A spreadsheet format is used throughout for the cost analysis. One example is an assembly process. It is proposed to rivet the aluminum frame used on a powerboat. The members of the frame are made from 16-gage aluminum. The buttonhead rivets, which are sized according to recommendations in Ref 12, are $\frac{5}{16}$ in. in diameter and conform to ANSI standards. Figure 2 shows the part.

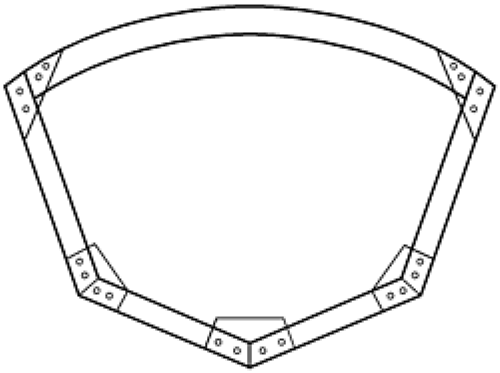

Fig. 2 Powerboat frame assembly

There are 20 rivets in the assembly, five large members of the frame, and five small brackets. Chapter 21 in Ref 7 includes six tables for setup, handling, pressing in the rivets, and riveting. A simple spreadsheet (for the first unit) might look like Table 2. The pieces are placed in a frame, the rivets are inserted, and riveted. The total cycle time for the first unit is 18.6 min. There are several points to mention here. First, the thickness of the material and the size of the rivets play no direct part in this simple calculation. The methods of Ref 7 do not include such details.

Table 2 Spreadsheet example for assembly of frame (Fig. 2)

Source[(a)]	Process description	Table time, min	Setup, min
21.2-S	Setup		15
21.2-1	Get 5 frame members from skid	1.05	
21.2-1	Get 5 brackets from bench	0.21	
21.2-2	Press in hardware (20 rivets)	1.41	
21.2-3	Set 20 rivets	0.93	
Total cycle time (minutes)		**3.60**	**15**

(a) Tables in Ref 7, Chapter 21

Yet common sense suggests that some of the details must count. For example, if the rivet holes are sized to have a very small clearance, then the "press-in-hardware" task, where the rivets are placed in the rivet holes, would increase. In a like manner, if the rivets fit looser in the rivet holes, the cycle time for this task might decrease. The point of this elementary discussion is that there is some implied tolerance with each of the steps in the assembly process.

In fact, one can deduce the tolerance from the standard specification of the rivets. From Ref 12, in the tolerance on $\frac{5}{16}$ in. diameter buttonhead rivets is 0.010 in. So the tolerance of the hole would be about the same size.

The second point is that there are 30 parts in this assembly. How the parts are stored and how they are placed in the riveting jig or fixture determines how fast the process is done. With experience, the process gets faster. There is a well-understood empirical model for process learning. The observation, often repeated in many different industries, is that inputs decrease by a fixed percentage each time the number of units produced doubles. So, for example, L_i is the labor in minutes of the *i*th unit produced, and L_0 is the labor of the first unit, then:

$$L_i = L_0 i^{\log\phi/\log 2} \quad \textbf{(Eq 11)}$$

The parameter ϕ measures the slope of the learning curve. The learning curve effects were first observed and documented in the aircraft industry, where a typical rate of improvement might be 20% between doubled quantities. This establishes an 80% learning function, that is, ϕ = 0.80. Because this example is fabricated from aluminum, with rivets typical of aircraft construction, it is easy to work out that the 32nd unit will require 32.7% of the time (6.1 min) compared to the first unit (18.6 min).

Learning occurs in any well-managed manual assembly process. With automated assembly, "learning" occurs only when improvements are made to the robot used. In either case, there is evidence that, over substantial production runs and considerable periods of time, the improvement is a fixed percentage between doubled quantities. That is, if there is a 20% improvement between the tenth and twentieth unit, there will likewise be a 20% improvement between the hundredth and two hundredth unit.

The cost engineer should remember that, according to this rule, the percentage improvement from one unit to the next is a steeply falling function. After all, at the hundredth unit, it takes another hundred units to achieve the same improvement as arose between the 10th and 20th units (Ref 13).

Complexity Theory

Up to now this article has dealt with the cost-estimation tools that do not require a complete description of the part or assembly to make the desired estimates. What can be said if the design is fully detailed? Of course, one could build a prototype to get an idea of the costs, and this is often done, particularly if there is little experience with the manufacturing methods to be used. For example, suppose there is a complex wave feed guide to be fabricated out of aluminum for a modern radar system. The part has some 600 dimensions. One could get a cost estimate by programming a numerically controlled milling machine to make the part, but is there a simpler way to get a statistically meaningful estimate of cost, while incorporating all of the design details? The method that fulfills this task is complexity theory.

There has been a long search for the "best" metric to measure how complex a given part or assembly is. The idea of using dimensions and tolerances as a metric comes from Wilson (Ref 14). The idea presented here is that the metric is a sum of log (d_i/t_i), where d_i is the ith dimension and t_i is its associated tolerance (i ranges over all the dimensions needed to describe the part). According to complexity theory, how complex a part is, *I*, is measured by:

$$I = \sum_i \log (d_i / t_i) \quad \textbf{(Eq 12)}$$

Originally, the log function was chosen from an imperfect analogy with information theory. It is now understood that the log function arises from a limit process in which tolerance goes to zero while a given dimension remains fixed. In this limit, if good engineering practice is followed, that is, if the accuracy of the machine making the part is not greatly different than the accuracy required of the part, and if the "machine" can be modeled like a first-order damped system, then it can be shown that the log function is the correct metric. Because of historical reasons, the log is taken to the base 2, and *I* is measured in bits. Thus Eq 12a is written:

$$I = \sum_i \log_2 (d_i / t_i) \quad \textbf{(Eq 12a)}$$

There are two main attractions of the complexity theory. First, *I* will include all of the dimensions required to describe the part. Hence, the metric captures all of the information of the original design. For assemblies, the dimensions and tolerances refer to the placement of each part in the assembly, and second, the capability of making rigorous statements of how *I* effects costs. In Ref 8 it is *proven* that if the part is made by a single manufacturing process, the average time (*T*) to fabricate the part is:

$$T = A \cdot I, \quad A = \text{const} \quad \textbf{(Eq 13)}$$

Again, in many cases, the coefficient *A* must be determined empirically from past manufacturing data. The same formula applies to assemblies made with a single process, such as manual labor. The extension to multiple processes is given in Ref 8.

A final aspect of complexity theory worth mentioning is risk. Suppose a part with hundreds of dimensions is to be made on a milling machine. The exact sequence in which each feature of the part is cut out will determine the manufacturing time. But there are a large number of such sequences, each corresponding to some value of *A*. Hence there is a collection of *A*s, which have a mean that corresponds to the average time to fabricate the part. That is the meaning of Eq 13.

It can be shown that the standard deviation of manufacturing time is:

$$s_T = \sigma_A I \quad \textbf{(Eq 14)}$$

where σ_T is the standard deviation of the manufacturing time, and σ_A is the standard deviation of the coefficient *A*. σ_A can be determined from past data. These results have a simple interpretation: Parts or assemblies with tighter (smaller) tolerances take longer to make or assemble because with dimensions fixed, the *log* functions increase as the tolerances decrease. More complex parts, larger *I*, take longer to make (Eq 13), and more complex parts have more cost risk (Eq 14). These trends are well known to experienced engineers.

In Eq 8, a large number of parts from three types of manufacturing processes were correlated according to Eq 13. The results of the following manual lathe process are typical of all the processes studied in Eq 8. Figure 3 shows the correlation of time with *I*, the dimension information, measured in bits. An interesting fact, shown in Fig. 4 is that the accuracy of the estimate is no different than that of an experienced estimator.

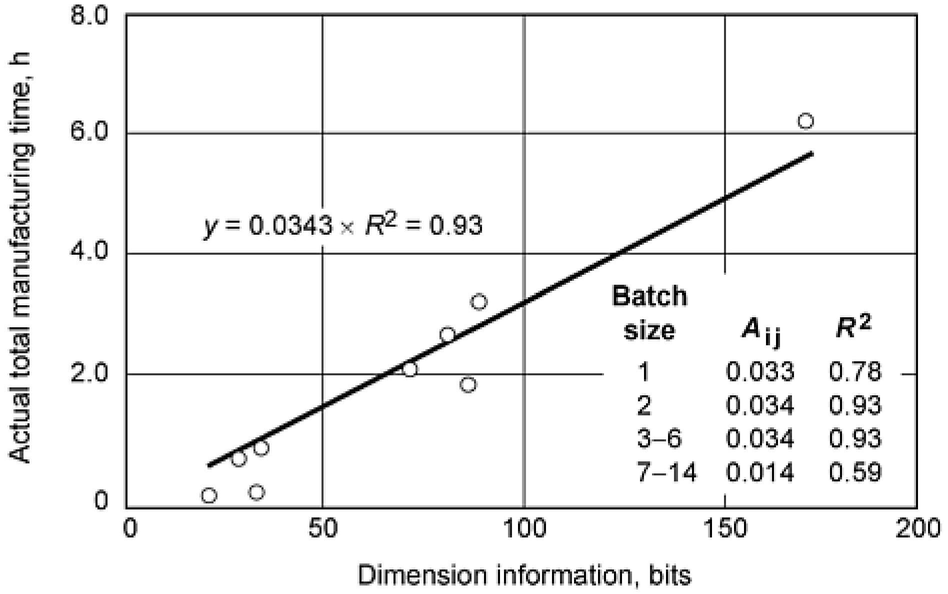

Fig. 3 Manufacturing time and dimension information for the lathe process (batch size 3 to 6 units)

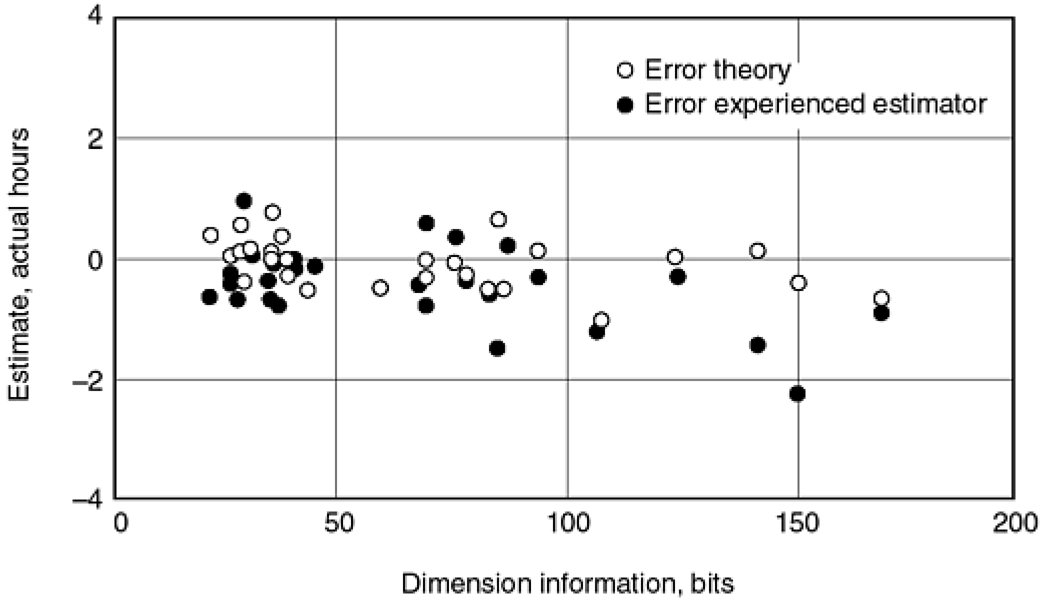

Fig. 4 Accuracy comparison for the lathe process

In Eq 13, the coefficient, *A*, is shown to depend on the machine properties such as speed, operation range, and time to reach steady-state speed. Can one estimate their value from first principals? It turns out that for manual processes one can make rough estimates of the coefficient.

The idea is based on the basic properties of human performance, known as Fitts' law. Fitts and Posner reported the maximum human information capacity for discrete, one-dimensional positioning tasks at about 12 bits/s (Ref 15). Other experiments have reported from 8 to 15 bits/s for assembly tasks (Ref 16).

The rivet insertion process discussed previously in this article is an example. The tolerance of the holes for the rivets is estimated to be 0.010 in., that is, the same as the handbook value of the tolerance of the barrel of the rivet (Ref 12). Then it is found that $d/t \approx 0.312/0.010 = 31.2$ and $\log_2 = 4.815$ bits for each insertion. The initial rate of insertion (Ref 7) was

20 units in 1.41 min. That corresponds to *A* = 1.14 bits/s. Clearly, there is some considerable improvement available if the maximum values quoted (Ref 15, 16) can be achieved for rivet insertion.

Example 3: Manual Assembly of a Pneumatic Piston.

In Ref 1 there is an extensive and helpful section on manual assembly. The method BDK used categorizes the difficulty of assembling parts by a number of parameters, such as the need to use one or two hands, the need to use mechanical tools, part symmetry, and so on. Figure 5 (reproduced from an example in Ref 17) shows the assembly of a small pneumatic piston. Table 3 lists assembly times.

Table 3 Assembly times for piston example (Fig. 5)

Part ID No.	No. times operation carried out	Handling code	Time, s	Insertion code	Insertion time, s	Total time, s	Pneumatic piston
7	1	30	1.95	00	1.5	3.45	Block
6	1	15	2.25	22	6.5	8.75	Piston
5	1	10	1.50	00	1.5	3.0	Piston stop
4	1	80	4.10	00	1.5	5.6	Spring
3	1	28	3.18	09	7.5	10.7	Cover
2	2	68	8.00	39	8.0	29.0	Screw
Total time: 60.5							

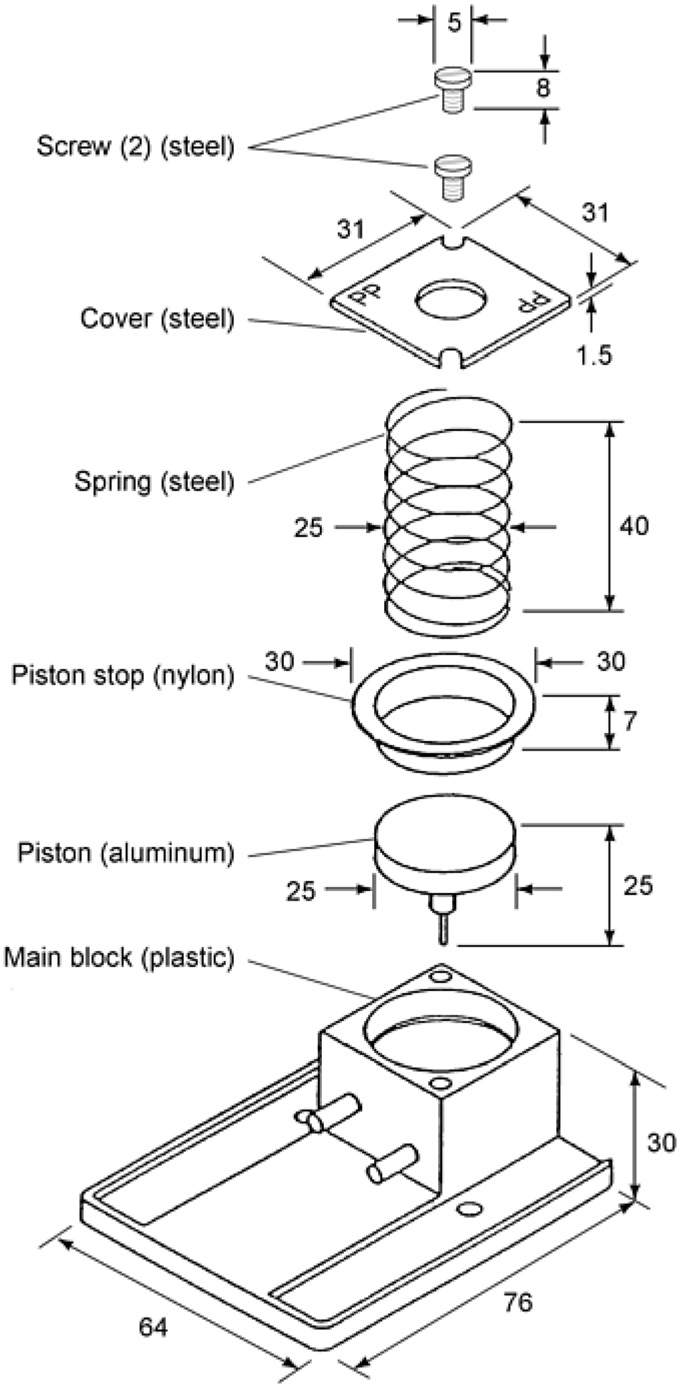

Fig. 5 Assembly of pneumatic piston. Dimensions in millimeters

Consider the entries for the two screws. The handling code, 68, describes a part with 360° symmetry that can be handled with standard tools. The insertion code, 39, describes a part not easy to align or position. The time for assembly of the screws is nominally 32 s, less an allowance of 31 s for repetitive operations.

Now consider a simplified design (Fig. 6 and Table 4). The same tables from Chapter 21 in Ref 7 are used as in Table 2. Software is available to automate the table look-up process. For the same problem using complexity theory, there is only one coefficient, A = 1.5 bits/s for the small manual assembly. This value is found by calculating the bits of information in the initial design and using the time found in Ref 17 to determine A.

Table 4 Assembly times for simplified piston design (Fig. 6)

Part ID No.	No. times operation carried out	Handling code	Time, s	Insertion code	Insertion time, s	Total time, s	Pneumatic piston
4	1	30	1.95	00	1.5	3.45	Block

Total time: 16.3							

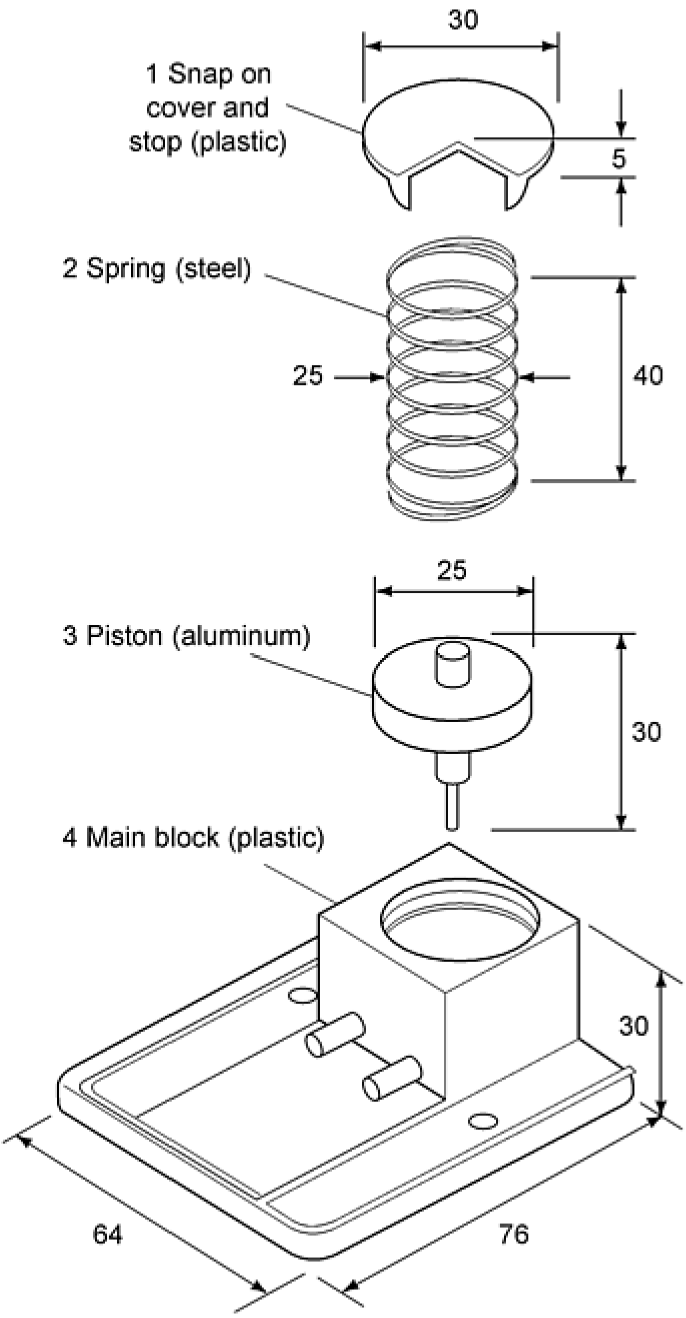

Fig. 6 Simplified assembly of pneumatic piston. Dimensions in millimeters

The tolerances were obtained in the following way. For the screws, the size was chosen to be M3X0.5--a coarse thread metric size consistent with insertion into molded nylon. As reported in Ref 12, the tolerance is ANSI B1.13M-1979.

The spring tolerance is derived using a standard wire size, 0.076 in. (0.193 mm), which gives a spring index D/d = 12.95, (D = spring diameter, d = wire diameter) well within the Spring Manufacturers Institute recommended range. The tolerance quoted is the standard tolerance for this wire diameter and spring index.

The plastic parts are presumed to be injection molded, with a typical tolerance of 0.1 mm. The screws are assumed to tighten to a tolerance of $\frac{60}{360} = \frac{1}{6}$ th of a turn.

These data, which can be easily verified in practice, give essentially the same results as the other empirical methods. Calculations for the original design (Fig. 5) and the simplified design (Fig. 6) are compared in Tables 5 and 6, respectively. This compares well with the results of Ref 17 (73% reduction) versus 76% reduction here.

Total:			**21.79302**	**% reduction 76.50281**

There are two comments to make:

- This method requires only one coefficient for hand assembly of small parts. $A \approx$1.6 bits/s and no look-up tables.
- One can make small changes in design, for example, change the screw size, and get an indication of the change in assembly time.

If one started with a preliminary design, the assembly time estimate would grow more accurate as more details of the design itself and the manufacturing process to build the design become known. However, the methods of Boothroyd, and others (Ref 1, 6, 17), require less data than does the complexity theory.

In the simplified manufacturing process, the coefficient A = 1.6 bits/s is substantially less than the Fitts' law (discussed earlier in this section on complexity theory) value of 8 bits/s. The discrepancy may lie in the time it takes an assembler to pick up and orient each part before the part is assembled. Jigs and trays, and so forth, that reduce this pick-and-place orientation effort would save assembly time. As before, there is some considerable improvement available if the maximum values quoted (Ref 15, 16) can be achieved for manual assembly. The value obtained here (A = 1.16) is close to that deduced from Ref 7 for the hand insertion of rivets.

Using complexity theory and a single assembly process, the ratio of the assembly times can be calculated with out any knowledge of the coefficient, *A*. Thus complexity theory offers advantages when a single process is used, even if little or nothing is known about the performance of the process.

Manufacturing Cost Estimating

David P. Hoult and C. Lawrence Meador, Massachusetts Institute of Technology

Cost Estimation Recommendations

Which type of cost estimate one uses depends on how much is know about the design. In the early stages of concept assessment of a new part or product, parametric methods, based upon past experience, are preferred. Risk is hard to quantify for these methods, because it can be very difficult to determine whether the new product really is similar to those used to establish the parametric cost model.

If there is some detailed information about the part or product, and the method of manufacturing is well known, then the empirical methods should be used. They can indicate the relative cost between different designs and give estimates of actual costs.

If detailed designs are specified, and a single manufacturing process is to be used, complexity theory should be used to compare the relative costs and cost risks of the different designs, even if the manufacturing process is poorly understood.

If there are detailed designs available, and well-known manufacturing methods are used, either complexity theory or empirical methods can be used to generate cost estimates. If a rigorous risk assessment is needed, complexity theory should be used.

Design for Casting

Thomas S. Piwonka, The University of Alabama

Introduction

CASTING offers the designer cost advantages over other manufacturing methods for most components, especially those having complex geometries. Casting properties are usually isotropic, and castings may be designed for function rather than for ease of assembly, like built-up structures. Fillet radii are usually generous, decreasing stress concentration factors. Converting a built-up assembly to a casting is usually accompanied by a decrease in part count, assembly time,

and inventory, and a savings in weight. With the development of rapid prototyping, expensive tooling is not necessary, and parts can be delivered within days after the order is placed. The casting process is well understood, and high integrity castings are as reliable as forgings. Indeed, castings prove their quality everyday in applications as demanding as prostheses, automotive chassis components, primary aircraft structures, and rotating hardware in gas turbine engines.

Designers face a number of challenges in the design of castings. To begin with, there are a wide variety of casting alloys. Complete mechanical property data, especially for dynamic properties, are sometimes lacking for these alloys. Static property data, though often found in handbooks, may consist of "typical values," which are of little help in creating an efficient design. These typical values obscure a crucial fact: casting properties are determined during solidification and subsequent heat treatment. This means that properties will vary depending on how quickly the casting solidifies and how the casting is heat treated.

Thus, to create effective designs, designers should be acquainted with fundamental information about how casting design influences casting solidification and how casting solidification influences casting properties. This article approaches design by reviewing the aspects of castings with which designers should be familiar. It also reviews methods used by foundries to produce high-integrity castings. Specification of casting quality levels should be based on solid knowledge of the effect of casting discontinuities and on component testing. Procurement of high-quality castings requires the involvement of the designer, the purchasing agent, and the foundry in a cooperative effort.

Design for Casting

Thomas S. Piwonka, The University of Alabama

Design Considerations

Casting design begins with the determination of the stresses that must be supported by the cast component and the geometrical constraints on that component. The designer then arranges the cast material to support the stresses in the most efficient way. However, in designing a part that will be cast, the designer will optimize the design by taking into account characteristics of the casting process. Because the properties of the casting determine its performance, those features of the casting process that affect the casting properties are reviewed here. This discussion emphasizes those concepts that designers and foundries can use to obtain maximum performance from cast parts.

Designers must begin the design process with a thorough understanding of what properties the component must have in addition to strength and ductility. Fundamental properties such as Young's modulus, Poisson's ratio, density, thermal conductivity, and coefficient of thermal expansion vary between alloy families and within alloy families. Cast alloy selection should begin by taking these differences into account.

How the Casting Process Affects Casting Properties. The properties of a component depend on the way it is made because the microstructure of the component depends on the manufacturing method, and the properties depend in turn on the microstructure. Thus the choice of making a part by casting, by forging, or by machining will affect the performance of the part. Once the decision is made on how the part is to be manufactured, the details of the processing parameters employed also affect component properties.

Component design is usually approached with the assumption that the material is uniform and isotropic and that there is an inherent small and random scatter in properties. Exceptions are made for fiber-reinforced composite materials and for components where directionality of properties is beneficial (directionally solidified gas turbine blades, for example). In castings, properties will be uniform in specific casting sections from casting to casting provided that the casting variables are constant for each casting. However, they may vary in a predictable manner from point to point within the casting.

Casting microstructure is determined by cooling rate, that is, how fast each part of the casting freezes. The cooling rate is roughly proportional to the ratio of the square of the surface area of the casting to the square of its volume (a consequence of what metal casters know as Chvorinov's law). In other words, bulky castings freeze much slower than thin castings--a sphere of a given volume will freeze more slowly than a thin plate of the same volume because the plate has much more surface area to transfer the same quantity of heat into the mold. Because the sphere solidifies more slowly, its microstructure will be coarser than that of the plate even if both are poured from the same melt at the same temperature. Because microstructure determines casting properties, the properties of the sphere and the plate will be different.

Casting is the solidification of liquid confined in a mold, which shapes the final component. A cavity is made in a mold, which may be a reusable aggregate, such as sand, or a metal mold, used in permanent mold and die casting. The metal is delivered to the mold cavity through channels in the mold or die, which are called *runners.* The passages between the runner and the mold cavity, where the metal enters the mold, are called *gates.*

Castings are frequently complex shapes made up of some bulky sections and some thin sections. Obviously, the thin sections will solidify faster than the thick sections; therefore, their properties will differ from those of the thick sections. Certain other geometric features will also influence solidification rate. For instance, concave sections, or reentrant angles, solidify more slowly than fins or protrusions, again affecting the resultant local structure and the properties. In other words, property variation within a casting, which is caused by local differences in cooling rate, is natural, expected, and entirely reproducible--it is not "random" scatter. It can be predicted and should be taken into account during component design to enhance the component performance.

One way to take account of this during the design phase is to apply a "section size" effect, a factor by which the local casting properties are adjusted based on local dimensions. While this technique is often effective, the designer should remember that casting properties depend on cooling rate, not section size. Cooling rate depends not only on section size but also on pouring temperature, mold material, gating system, the presence or absence of chills in the mold, mold coatings, and insulation. Thus, within limits (some very broad), the properties can be controlled by the metal caster to produce those which the designer desires.

Cast iron provides the most dramatic example of the differences in properties caused by differences in structure resulting from cooling rate differences. When cast iron (which is essentially a solution of carbon and silicon in iron) solidifies, the carbon can take different forms, depending on its composition and solidification rate and the way the metal has been treated during melting. Chill cast iron (white iron) has properties completely different from gray iron of the same composition, caused solely by the accelerated cooling rate in the "chilled" iron. White iron freezes so quickly that the carbon combines with the iron to solidify as the compound Fe_3C, known as *cementite* because it is hard and brittle. In gray iron, which solidifies more slowly, the carbon appears as graphite flakes; this iron is easy to machine.

Ductile iron also has properties significantly different from gray iron; in this case the carbon solidifies as tiny spheres in a steel matrix. Since the spheres of graphite are less effective as stress raisers, compared to the flakes of carbon in gray iron, ductile iron has significant ductility, whereas gray iron does not, even though they both may have nearly identical compositions. In this case, the difference in structure, which produces the property difference, is caused not by cooling rate, but by chemical treatment of the melt, which alters the undercooling at the beginning of solidification, which in turn affects the way the carbon solidifies. It is important here to realize that in castings, similar compositions, in similar geometries, can have very different properties, depending on the way the castings are made.

Designers frequently use handbook data in designing components. Very often, these data are developed using Gaussian statistics. As noted above, such data can be misleading if not corrected to reflect differences in cooling rate from section to section within a casting. Gaussian statistics are appropriate for those materials that are truly ductile, meaning those that have a tensile elongation over 8 to 10%. Many casting alloys, however, when completely free of discontinuities, have elongations of only 5 to 10%. Indeed, this is often the reason that these alloys are commonly cast: their low ductilities make them hard to form by forging or machining. Use of Gaussian statistics to determine design allowables in these alloys is incorrect, leads to "casting factors," and causes significant overdesign, waste of material, and weight penalties. Casting factors are arbitrary increases in casting section thickness applied to compensate for perceived lack of reproducibility of casting properties. Such factors are unnecessary and wasteful (Ref 1). For this reason, it is important that designers recognize that designing with low ductility (not brittle) materials requires a different approach than designing with ductile materials. Also, casting versions of wrought alloys may have different compositions than the wrought alloys to aid in solidification.

Reproducibility of properties produced by a process is most important for the designer because the components that are designed must behave according to the design. Reliability is often evaluated using Weibull statistics (Ref 2), which consider the probability of the existence of a discontinuity that would cause failure. This is particularly appropriate for the design of low ductility materials. In analyzing data using Weibull statistics, one evaluates the value of the Weibull modulus. The higher the Weibull modulus is, the more reliable the material will be (that is, the higher the Weibull modulus, the less the variation in property within a given section of the component).

For tensile properties, ceramics typically have Weibull moduli of approximately 10. Aluminum alloy forgings typically have Weibull moduli of approximately 50. Conventionally cast aluminum castings have Weibull moduli of approximately 30; using techniques for "premium quality castings," castings with Weibull moduli of 50 are routinely produced for use as

primary structures for commercial aircraft (Ref 3, 4). For carefully made thin sections, the Weibull modulus can be above 80 (Ref 5), well above that expected for forgings.

Ductile iron, most cast steel alloys, and copper-base alloys commonly have high ductilities, and the use of Gaussian statistics to determine design allowables is appropriate. However, gray and compacted graphite iron, superalloys, some tool steels, and many aluminum alloys are low ductility alloys and should be approached using Weibull statistics.

Basic Features of Solidification. Solid and liquid alloys usually have different densities, which means when solidification is complete, the solid will occupy less space than the liquid (in most alloys). In other words, the solid "shrinks." Because solid metal is more dense than liquid metal, the metal shrinks when it solidifies, and the final casting will not fill the mold unless this shrinkage is compensated. To do this, the foundry adds a *riser* to the casting. This riser is a reservoir of molten metal, which supplies liquid metal to the solidifying casting and compensates for the shrinkage that occurs. If the riser is to function properly, the liquid metal that it contains must be able to flow through the solidifying casting to reach the areas in the casting where solidification and hence shrinkage is occurring.

In alloy solidification, the picture is complicated by the fact that alloys freeze over a range of temperatures. This means that small nuclei of solid grains form at the beginning of solidification and grow (forming *dendrites,* the term for solidifying grains) as the temperature in the casting falls and solidification progresses. As these grains grow, they form a "mush" of liquid and solid, which becomes progressively more solid until solidification is complete. Because each small dendrite that forms is a site where shrinkage occurs during solidification, feeding the shrinkage means finding a way to cause metal to flow between the dendrites to the location where solidification (and shrinkage) is taking place. As the dendrites grow, the paths that deliver liquid metal from the riser to the areas where solidification is taking place become smaller until they are at last too narrow to allow metal to pass. (There is one exception to this rule. In cast iron, both gray and ductile, the graphite that solidifies expands on solidification. Because graphite forms at the end of solidification, its expansion often (but not always) compensates for the shrinkage of the iron. For this reason, cast iron often needs very little in the way of risers.)

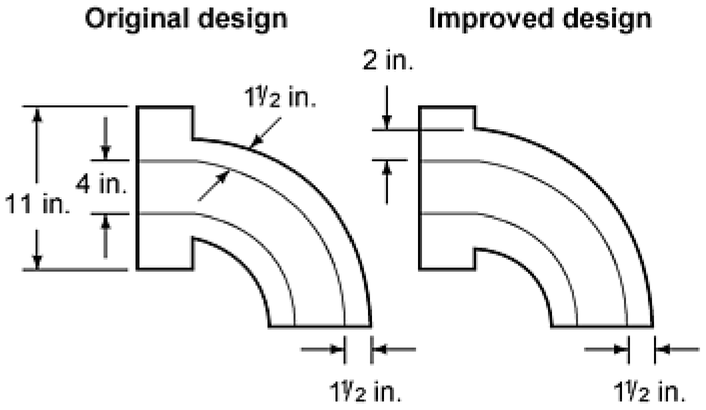
Liquid metal can dissolve much more gas in solution than solid metal. Therefore, when metal solidifies, gas that is present in the liquid is rejected and forms bubbles. A commonly encountered example is that of hydrogen in aluminum. If these bubbles are trapped in the casting when it freezes, the result is a pore. Pores that result from gas may be spherical, indicating that they formed early in solidification when the metal was mostly liquid, or they may be interdendritic in shape, showing that they formed late in solidification, when the liquid that remained was present between dendrites.

As the solidification rate increases, the microstructure of the casting is refined. That is, the grains are smaller, and the spacing between the arms of the dendrites that make up grains is finer. Mechanical properties usually improve as the microstructure becomes finer. Because the properties depend on the microstructure, which depends on the solidification rate, which in turn depends on the processing variables used by the foundry and the casting design, designers have a major influence on the final properties of the casting.

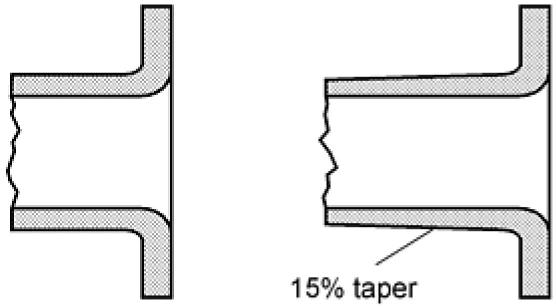
Using solidification simulation programs, foundries predict how fast each section of each casting will solidify and, therefore, what will be the properties of each section. The use of these programs combined with the application of statistical process control techniques has transformed casting into a high technology manufacturing process capable of reliably producing critical components for the most demanding applications.

General Design Considerations for Castings. Casting design influences the way the casting solidifies because the geometry of the casting influences how fast each section solidifies; therefore, it is a major factor in determining how castings will perform. The overarching principle of good casting design is that casting sections should freeze progressively, allowing the risers to supply liquid metal to feed shrinkage that occurs during solidification. There are a number of excellent summaries of principles of good casting design (Ref 6, 7, 8), and a comprehensive booklet was published on design of premium quality aluminum alloy castings (Ref 9). This latter publication also includes general information on the specification and process of approving foundry sources, which is applicable to castings made from any metal.

Designing for progressive solidification requires tapering walls so that they freeze from one end to the other, as shown in Fig. 1, and avoiding situations where two heavy sections are separated by a thin section. (This is a poor design because metal must feed one heavy section through the thin section; when the thin section freezes before the heavy section, the flow path will be cut off and shrinkage may form in the heavy section.)



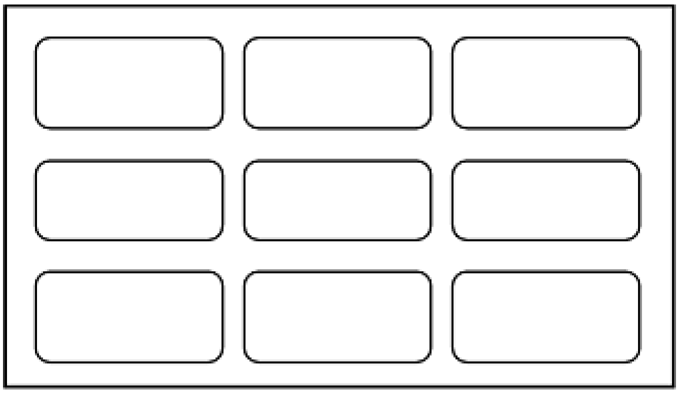
(a)



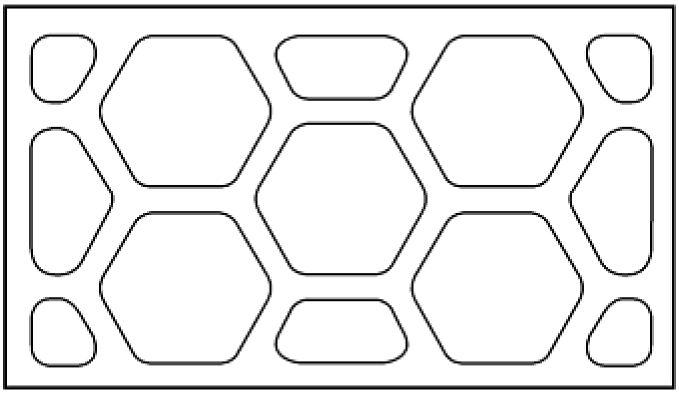
(b)

Fig. 1 Redesign of castings to provide progressive solidification through the use of tapered walls. (a) Elbow design. (b) Valve fitting design. Source: Ref 10

Junctions also concentrate heat, leading to areas in the casting where heat is retained. These areas solidify more slowly than others, thus having a coarser structure and different properties from other sections, and solidify after the rest of the casting has solidified, so that shrinkage cannot be fed. Minimizing the concentration of heat in junctions, therefore, aids in improving casting properties. Examples of this are shown in Fig. 2.



(a)



(b)

Fig. 2 Redesign of a casting to minimize heat concentration. (a) Design has numerous hot spots (X junctions) that will cause the casting to distort. (b) Improved design using Y junctions. Source: Ref 6

Concave corners concentrate heat, so they freeze later and more slowly than straight sections, while convex corners lose heat faster, and freeze sooner and more quickly than straight sections. In designing a casting, the designer should use properties from test bars that have solidified at the actual cooling rate in that section of the casting. This cooling rate can be determined by instrumenting a casting and measuring the cooling rate in various sections or by simulating its solidification using a commercial solidification simulation program.

The hollow spaces in castings are formed by *cores,* refractory shapes placed in the molds and around which the casting freezes. These cores are later removed from the casting, usually by thermal or mechanical means. However, each core requires tooling to form it and time to place it in the mold. Casting designs that minimize cores are preferable to minimize costs. Some examples are given in Fig. 3.

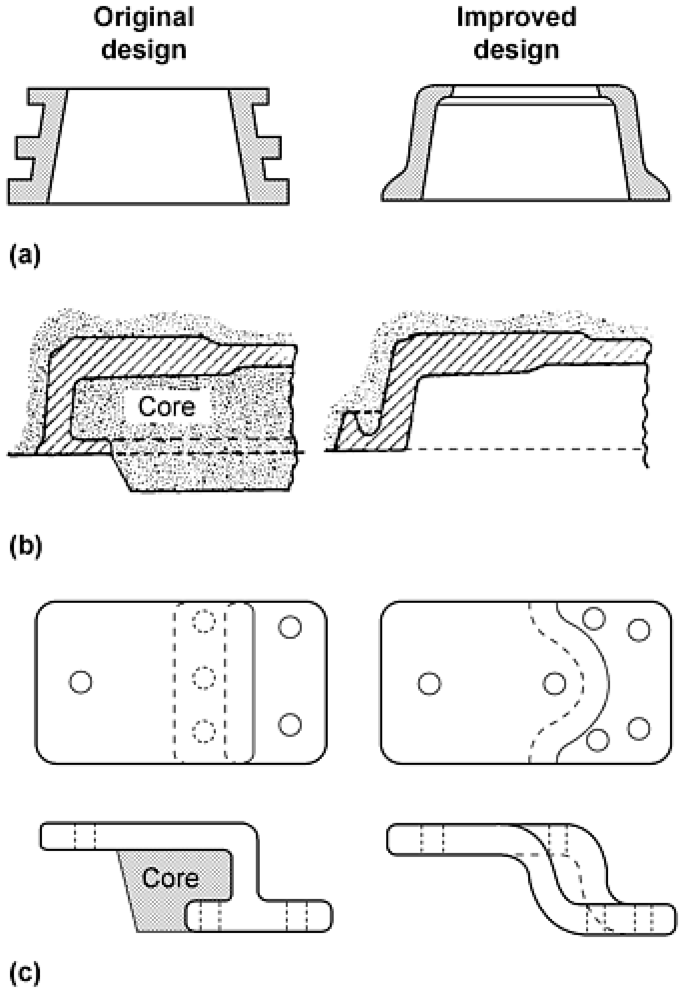


Fig. 3 Redesign of castings to eliminate cores. (a) Casting redesigned to eliminate outside cores. (b) Simplification of a base plate design to eliminate a core. (c) Redesign of a bracket to eliminate a core and to decrease stress problems. Source: Ref 10

The designer must provide surfaces for the attachment of gates and risers. The casting must solidify toward the riser in order to be sound, and gates must be located so that the mold fills from the bottom to the top so that oxide films that form are swept to the top surface of the casting or into risers where they will not affect casting properties. Gate and riser locations must be accessible for easy removal to minimize processing costs. The position of gate and riser contacts may also add costs if they are placed where subsequent machining will be required to remove gate stubs or riser pads in the finished component.

Design for Casting

Thomas S. Piwonka, The University of Alabama

The Effect of Casting Discontinuities on Properties

Poor casting design can interfere with the ability of the foundry to use the best techniques to produce reliable castings. The designer also specifies the quality requirements that ensure that the cast component will perform as desired. Over specification causes needless expense and can be avoided by understanding the effect of discontinuities on casting performance and the effect of casting design on the tendency for discontinuities to form during the casting process. Important types of casting discontinuities include porosity, inclusions, oxide films, second phases, hot tears, metal penetration, and surface defects.

Porosity is a common defect in castings and takes many forms. Pores may be connected to the surface, where they can be detected by dye penetrant techniques, or they may be wholly internal, where they require radiographic techniques to discover. *Macroporosity* refers to pores that are large enough to see with the unaided eye on radiographic inspection, while *microporosity* refers to pores that are not visible without magnification.

Both macroporosity and microporosity are caused by the combined action of metal shrinkage and gas evolution during solidification. It has been shown (Ref 11, 12) that nucleation of pores is difficult in the absence of some sort of substrate, such as a nonmetallic inclusion, a grain refiner, or a second phase particle. This is why numerous investigations have shown that clean castings, those castings that are free from inclusions, have fewer pores than castings that contain inclusions. Microporosity is found not only in castings, but also in heavy section forgings that have not been worked sufficiently to close it up.

When the shrinkage and the gas combine to form macroporosity, properties are deleteriously affected. Static properties are reduced at least by the portion of the cross-sectional area that is taken up with the pores (since there is no metal in the pores, there is no metal to support the load there, and the section acts as though its area was reduced). Because the pores may also cause a stress concentration in the remaining material (Ref 13, 14), static properties may be reduced by more than the percentage of cross-sectional area that is caused by the macroporosity.

Dynamic properties are also affected. A study of aluminum alloys showed that fatigue properties in some were reduced 11% when specimens having x-ray quality equivalent to ASTM E 155 level 4 were tested, and that they were reduced 17% when specimens having quality of ASTM E 155 level 8 were tested (Ref 15).

Static properties are mostly unaffected by microporosity. Microporosity is found between dendrites and, like macroporosity, is caused by the inability of feed metal to reach the interdendritic areas of the casting where shrinkage is occurring and where gas is being evolved. However, because this type of porosity occurs late in solidification, particularly in long-range freezing (mushy-freezing) alloys, it is particularly difficult to eliminate. The most effective method is to increase the thermal gradient (often accomplished by increasing the solidification rate), which decreases the length of the mushy zone. This technique may be limited by alloy and mold thermal properties, and by casting geometry, that is, the design of the casting.

As long as the micropores are less than 0.2 mm in length, there is no effect on dynamic properties; fatigue properties of castings with pores that size or smaller are in the same range as those of castings where no micropores were found (Ref

16, 17, 18). The shape of the micropore is as important as its size, with elongated pores having a greater effect than round pores (Ref 19). Areas where microporosity is expected can be predicted by solidification modeling, similar to the prediction of macroporosity (see below). Microporosity can be healed by hot isostatic pressing (HIP). In one study comparing HIP and non-HIP samples, no difference was found in fatigue lives of HIP and non-HIP samples (Ref 20). However, the HIP samples showed a lower crack growth rate than non-HIP samples. In another study (Ref 21), HIP improved fatigue crack growth resistance only close to threshold levels. (Additional information about HIP is provided in the section "Hot Isostatic Pressing" in this article.) As noted above, the design of the casting directly affects its tendency to solidify in a progressive manner, thereby affecting both the quality and the price of the cast component.

Porosity and casting costs are minimized in casting designs that emphasize progressive solidification toward a gate or riser, tapered walls, and the avoidance of hot spots.

Inclusions are nonmetallic particles that are found in the casting. They may form during solidification as some elements (notably manganese and sulfur in steel) precipitate from solution in the liquid. More frequently, they are formed before solidification begins. The former are sometimes called *indigenous* inclusions, and the latter are called *exogenous* inclusions. Inclusions are ceramic phases; they have little ductility. A crack may form in the inclusion and propagate from the inclusion into the metal, or a crack may form at the interface between the metal and the inclusion. In addition, because the inclusion and the metal have different coefficients of thermal expansion, thermally induced stresses may appear in the metal surrounding the inclusion during solidification (Ref 22). As a result, the inclusion acts as a stress concentration point and reduces dynamic properties. As in the case of microporosity, the size of the inclusion and its location determine its effect (Ref 23, 24). Small inclusions that are located well within the center of the cross section of the casting have little effect, whereas larger inclusions and those located near the surface of the casting may be particularly detrimental to properties. Inclusions may also be a problem when machining surfaces, causing excessive tool wear and tool breakage.

Exogenous inclusions are mostly oxides or mixtures of oxides and are primarily slag or dross particles, which are the oxides that result when the metal reacts with oxygen in the air during melting. These are removed from the melt before pouring by filtration. Most inclusions found in steel castings arise from the oxidation of metal during the pouring operation (Ref 25). This is known as *reoxidation,* and takes place when the turbulent flow of the metal in the gating system causes the metal to break up into small droplets, which then react with the oxygen in the air in the gating system or casting cavity to form oxides. Metal casters use computer analysis of gating systems to indicate when reoxidation can be expected in a gating system and to eliminate them. However, casting designs that require molten metal to "jet" through a section of the casting to fill other sections will recreate these inclusions and should be avoided.

Oxide films are similar to inclusions and have been found to reduce casting properties (Ref 3, 4, 5). These form on the surface of the molten metal as it fills the mold. If this surface film is trapped within the casting instead of being carried into a riser, it is a linear discontinuity and an obvious site for crack initiation. It has been shown (Ref 26, 27) that elimination of oxide films, in addition to substantially improving static properties, results in a five-fold improvement of fatigue life in axial tension-tension tests.

Oxide films are of particular concern in nonferrous castings, although they also must be controlled in steel and stainless steel castings (because of the high carbon content of cast iron, oxide films do not form on that metal). If the film folds over on itself as a result of turbulent flow or "waterfalling" (when molten metal falls to a lower level in the casting during mold filling), the effects are particularly damaging. Casting design influences how the metal fills the mold, and features of the design that require the metal to fall from one level to another while the mold is filling should be avoided so that waterfalls are eliminated. Oxide films are avoided by filling the casting from the bottom, in a controlled manner, by pumping the metal into the mold using pneumatic or electromagnetic pumps. If the casting is poorly designed, waterfalling will result. An example is given in Fig. 4.

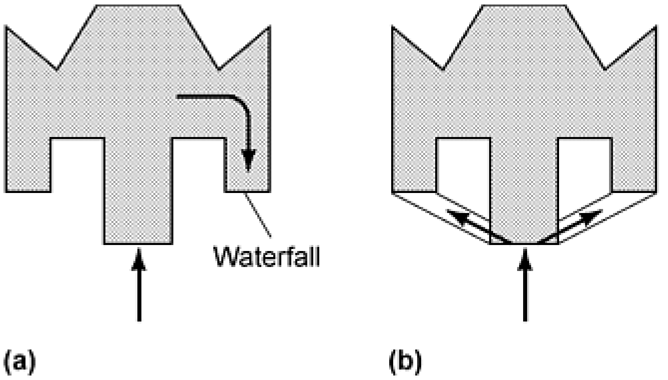

Fig. 4 Redesign of a casting to avoid waterfalling. (a) In this design, waterfalling results when casting is filled from the bottom. (b) Improved design provides a path for the metal to follow as it fills the mold.

Second phases, which form during solidification, may also nucleate cracks if they have the proper size and morphology (Ref 28). An example is aluminum silicon alloys, where the silicon eutectic is present as large platelets, which nucleate cracks, and along which cracks propagate (Ref 29, 30). The size of these platelets may be significantly reduced by modifying the alloy with additions of sodium or strontium. However, such additions increase the size of micropores (Ref 31), and for this reason, many foundrymen rely on accelerated solidification of the casting to refine the silicon. As noted above, solidification rates normally increase, and the structure is thus refined, in thin sections. Heavy sections are to be avoided if a fine structure is desired. Generally speaking, however, secondary phases in the structure of castings become important in limiting mechanical behavior of castings only in the absence of nonmetallic inclusions and microporosity (Ref 32).

Hot tears form when casting sections are constrained by the mold from shrinking as they cool near the end of solidification. These discontinuities are fairly large and are most often weld repaired. If not repaired, their effect is not readily predictable (Ref 17). While generally they are detrimental to casting properties, under some circumstances they do not affect them. Hot tears are caused by a combination of factors, including alloy type, metal cleanliness, and mold and core hardness. However, poor casting design is the primary cause. Castings should be designed so that solidifying sections are not subjected to tensile forces caused by shrinkage during solidification, as the solidifying alloy has little strength before it solidifies. An example is given in Fig. 5, and an extensive discussion on how to prevent hot tears through casting design is provided in Ref 34.

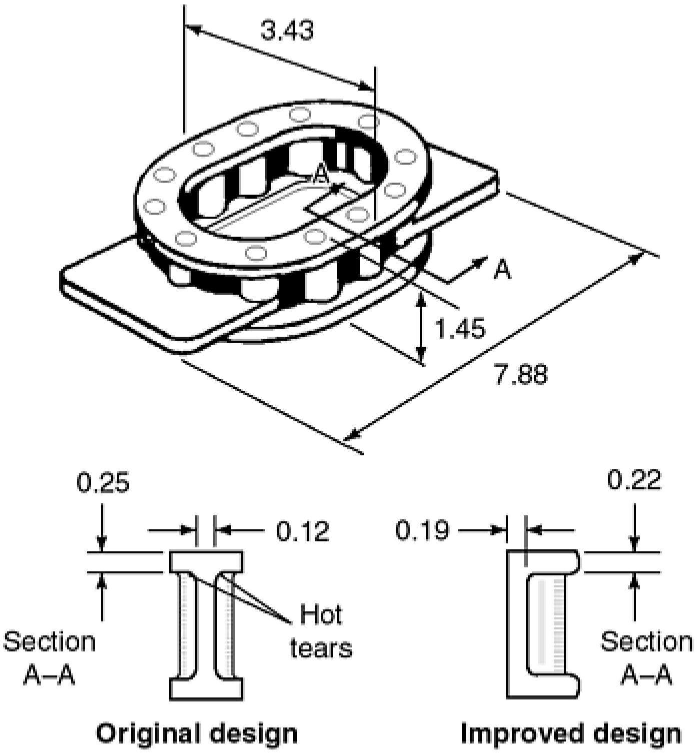

Fig. 5 Redesign of a casting to eliminate hot tears. Mold restraint coupled with nonuniform freezing of the various sections of this aluminum alloy 356 casting resulted in hot tears. Moving the wall and increasing its thickness corrected the problem. Part dimensions in inches. Source: Ref 33

Metal Penetration. Molten metal may penetrate the surface of the mold, forming a rough surface or, in extreme cases, actually becoming intimately mixed with the sand in the mold. In iron castings, this is normally the result of the combination of metallostatic head (the pressure exerted on the molten iron at the bottom of the mold by the weight of the metal on top of it) and the surface tension relationships between the liquid iron and molding materials (Ref 35). In cast iron, it is frequently also the result of the expansion of graphite at the end of solidification, forcing liquid metal into the mold if the casting is not properly designed with a tapered wall to promote directional solidification and avoid hot spots.

Surface Defects. Surface finish is also an important specification. Surface discontinuities affect fatigue life (Ref 36, 37), and obviously smoother surfaces are superior to rough surfaces. Designers should be certain that fatigue data used in design calculations has been taken from as-cast surfaces rather than machined surfaces, as most surfaces on castings where stress concentrations might be expected are not machined. Surface finish in castings is controlled by the application of coatings to the mold as well as proper selection of mold materials. Metal mold casting processes generally produce better surfaces than sand casting processes.

Design and Service Considerations. The existence of casting discontinuities does not, in and of itself, indicate that casting performance in service will be affected. Equally important are the size, location, and distribution of these discontinuities (Ref 18, 38, 39, 40). Those discontinuities that are small and located near the center of the casting have little effect, while those located at or near the surface of the casting are usually damaging. Clustered discontinuities and those that occur in a regular array have a greater effect on properties than those that are isolated and randomly distributed.

In specifying acceptable levels of discontinuities, such as microporosity and inclusion sizes and distribution, the designer should determine the critical flaw size that will deleteriously affect performance in service. This permits the foundry to design a casting practice that will eliminate such discontinuities at minimum cost.

Design for Casting

Thomas S. Piwonka, The University of Alabama

Casting Tolerances

Casting tolerances depend on the alloy being poured, the size of the casting, and the molding method used. Generally speaking, casting dimensional accuracy increases as one moves to the right in Fig. 6 and as the casting dimensions decrease. However, there is significant overlap between processes, and new developments are continually being made so that even this general trend may not apply for a specific cast component. In addition, evidence is mounting that most foundries produce castings that are more accurate dimensionally than called for in casting specifications. For this reason, designers should consider more than one casting process during the design stage and select a process that offers the best combination of dimensions, properties, and cost. Each casting process has its particular strengths, and designers should acquaint themselves with each (Ref 41). Table 1 lists factors that affect the selection of an appropriate casting process for aluminum alloy parts. Additional information on the selection of casting processes is provided in the article "Manufacturing Processes and Their Selection" in this Volume.

Table 1 Factors affecting selection of casting process for aluminum alloys

Factor	Casting process		
	Sand casting	**Permanent mold casting**	**Die casting**
Cost of equipment	Lowest cost if only a few items required	Less than die casting	Highest
Casting rate	Lowest rate	11 kg/h (25 lb/h) common; higher rates possible	4.5 kg/h (10 lb/h) common; 45 kg/h (100 lb/h) possible
Size of casting	Largest of any casting method	Limited by size of machine	Limited by size of machine
External and internal shape	Best suited for complex shapes where coring required	Simple sand cores can be used, but more difficult to insert than in sand castings	Cores must be able to be pulled because they are metal; undercuts can be formed only by collapsing cores or loose pieces
Minimum wall thickness	3.0-5.0 mm (0.125-0.200 in.) required; 4.0 mm (0.150 in.) normal	3.0-5.0 mm (0.125-0.200 in.) required; 3.5 mm (0.140 in.) normal	1.0-2.5 mm (0.100-0.040 in.); depends on casting size
Type of cores	Complex baked sand cores can be used	Reuseable cores can be made of steel, or nonreuseable baked cores	Steel cores; must be simple and straight so they can be pulled

		can be used	
Tolerance obtainable	Poorest; best linear tolerance is 300 mm/m (300 mils/in.)	Best linear tolerance is 10 mm/m (10 mils/in.)	Best linear tolerance is 4 mm/m (4 mils/in.)
Surface finish	6.5-12.5 μm (250-500 μin.)	4.0-10 μm (150-400 μin.)	1.5 μm (50 μin.); best finish of the three casting processes
Gas porosity	Lowest porosity possible with good technique	Best pressure tightness; low porosity possible with good technique	Porosity may be present
Cooling rate	0.1-0.5 °C/s (0.2-0.9 °F/s)	0.3-1.0 °C/s (0.5-1.8 °F/s)	50-500 °C/s (90-900 °F/s)
Grain size	Coarse	Fine	Very fine on surface
Strength	Lowest	Excellent	Highest, usually used in the as-cast condition
Fatigue properties	Good	Good	Excellent
Wear resistance	Good	Good	Excellent
Overall quality	Depends on foundry technique	Highest quality	Tolerance and repeatability very good
Remarks	Very versatile as to size, shape, internal configurations	. . .	Excellent for fast production rates

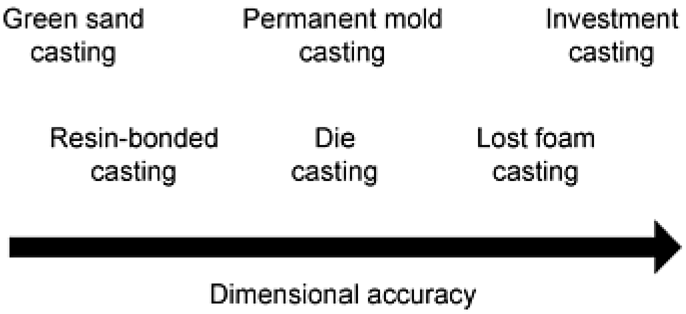

Fig. 6 General relationship between dimensional accuracy and casting process

Casting design also affects tolerances. Critical dimensions should not cross parting lines in molds or injection or core dies. The choice of pattern materials also can affect dimensional tolerances.

Stresses that arise from unequal contraction of parts of the casting as it cools from solidification temperatures (Ref 43), as well as those that result from heat treating (Ref 44) can distort castings so that they no longer conform to design dimensions. This also affects tolerances and may lead to extra costs to straighten castings. Solidification stresses are caused by shrinkage during casting solidification when different sections of the casting solidify at different times and rates. Because casting solidification rates depend on the casting design, the designer should consider the effect of the component design on casting distortion. Some examples are given in Fig. 7.

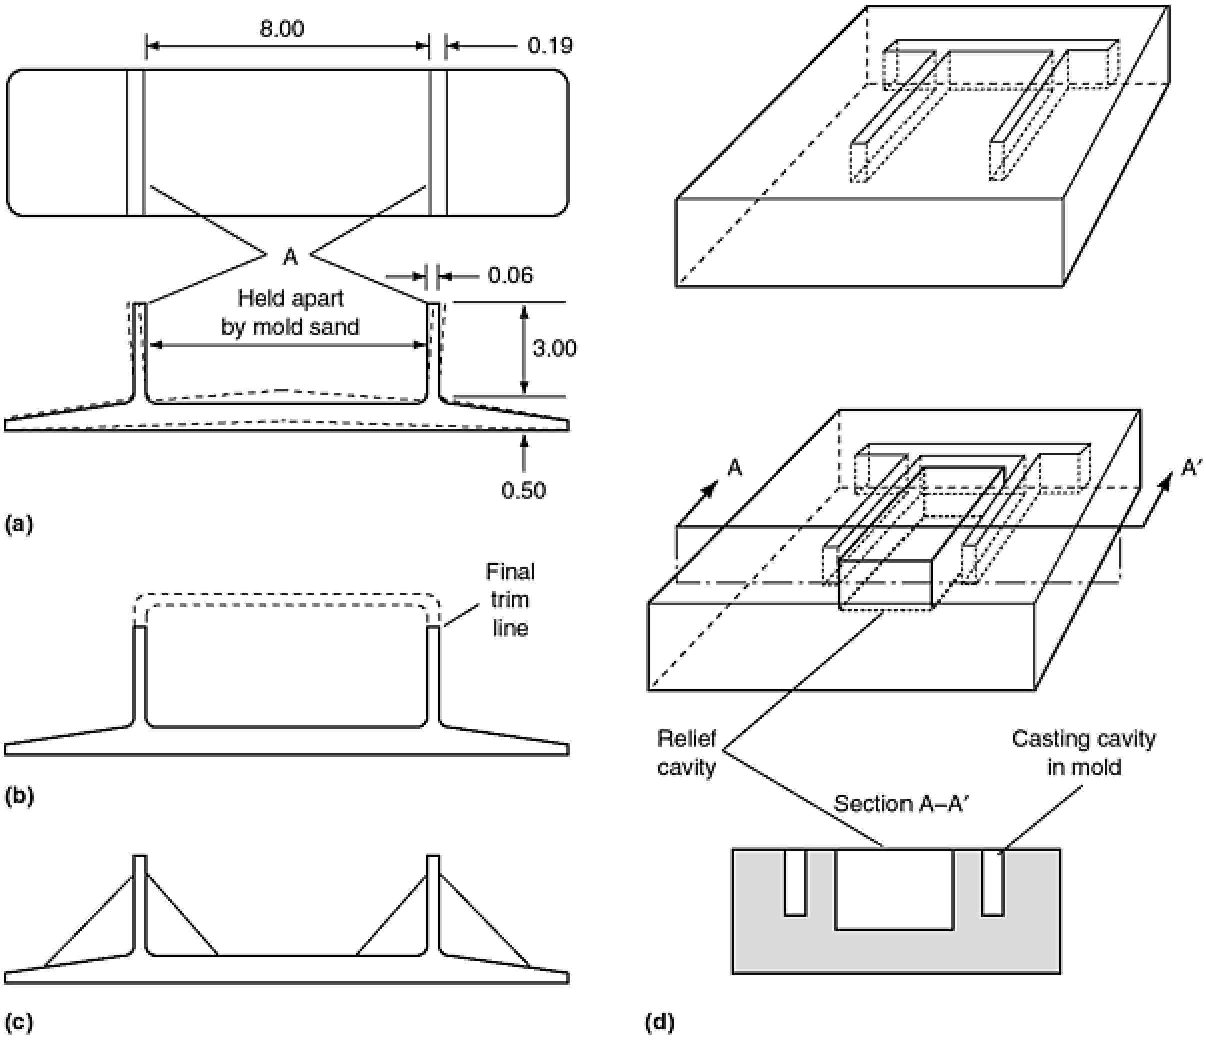

Fig. 7 Designing castings to prevent distortion caused by mold restraint. The original design, shown in top and front views in (a), was altered to three possible preventative designs, as follows. (b) Preferred method incorporating a tie bar. (c) Less effective method than that shown in (b). (d) Open cavity created in the molding media to relieve restraint upon flanges during casting solidification by allowing solid sand mass to collapse during shrinkage and minimize restraint. Dimensions given in inches. Source: Ref 45

Hot Isostatic Pressing

Occasionally, there are applications where designers require that casting soundness be 100% of theoretical density. For those castings, HIP is recommended. In HIP treatments, the castings are placed in a pressure vessel, and an inert gas is introduced, partially pressurized, and heated while it is confined to the pressure vessel. The gas, unable to expand, increases in pressure and exerts this pressure on the surface of the casting. As the casting is softened by the heat, internal voids collapse under the pressure.

Hot isostatic pressing treatment is relatively inexpensive. If the porosity to be healed is relatively large (macroporosity), HIP will form small dimples on the surface of the casting that may require weld repair. Because HIP is a thermal as well as a pressure treatment, it can alter the microstructure (and therefore the properties) of components if not carefully designed. Hot isostatic pressing will not affect inclusions or oxide folds and, therefore, will not repair castings that have those types of discontinuities. It also has no effect on pores that are connected to the surface. Hot isostatic pressing has made possible the use of alloys that, because of their composition, do not solidify pore free and, without HIP, could not be used for high-integrity applications.

Design for Casting

Solidification Simulation and Its Use in Designing Castings

This article has emphasized the importance of the casting design in influencing the way the casting solidifies and, thus, the cast structure and the properties that are produced. Since the cast structure controls the heat treated structure and the final structure controls the properties of the component, it is clear that successful design of castings means that the designer must be able to predict the effect of the design on the structure of the final part. This is done today by using solidification simulation models. Most progressive foundries today use simulation models in engineering the casting process. Designers are encouraged to work with foundries and have them run solidification models on their designs in a concurrent design process to engineer castings that perform satisfactorily and are reasonably priced.

Solidification simulation models have been extensively developed over the last twenty years, and today there are a large variety of them (Ref 46). The more elementary models are based on Chvorinov's law and operate by comparing surface area to volume ratios of adjoining casting sections to predict the order in which the sections solidify (that is, how progressive the solidification will be). Those models are satisfactory for predicting whether or not macroporosity will form on solidification; some models are also effective at predicting the location of microporosity.

Advanced models use finite element or finite difference methods to predict how the casting fills and, from those results, are able to establish the temperature of each point in the mold and each point in the liquid metal at the start of solidification. From this, a more accurate picture of the way the casting solidifies is possible. These models are also capable of predicting the grain size and structure and are now being used to predict casting properties that result from a specific casting design and manufacturing process. Solidification models today are capable of predicting the distortion that will occur during casting and heat treatment and can be used to minimize residual stresses. Some of the commercial packages include expert systems to help orient the casting in the mold to minimize casting defects and to suggest gating and risering schemes.

These models are a powerful tool for concurrent engineering of cast components. The designer, working with the foundry, can see how the casting will solidify before the casting is poured. If problem areas are found with the design, it can be altered, and the new design can be simulated. This iteration can be repeated until a satisfactory design is developed. When these simulations are combined with rapid prototyping methods, expedited delivery of cast components can be achieved.

The designer must begin the design of a casting with an understanding of what properties are desired and required throughout the cast component. Flaw sizes must be kept below the critical level, and the designer should know what that level is. Critical flaw sizes will vary according to location in the casting; that information should be reflected in specifications that also vary by location in order to minimize manufacturing costs.

Casting design influences how the castings solidify and, hence, the properties that are obtained. Many collections of casting data in handbooks overlook the effect of cooling rate on casting performance and, as a result, do not provide adequate information for designers. Designers are therefore encouraged to work with foundries to develop data bases of reliable mechanical property data that reflect the effect of cooling rates of the alloy and the sections that the designer intends to use. This is particularly important for areas of the casting where stress concentrations are likely; use of a solidification simulation program should ensure that these areas are not also areas of slow solidification.

Designers should be aware that different casting alloys have different levels of "castability," meaning that development of reliable casting properties may be more difficult in some alloys than others. Specification of a casting alloy solely on the results of test bar data (test bars are easy to cast and often do not reflect casting problems encountered in actual castings) without consulting the metal caster can lead to high casting costs as the foundry compensates for castability difficulties with the alloy.

Thomas S. Piwonka, The University of Alabama

Conclusions

The casting process offers the designer exceptional design flexibility at reasonable cost. The designer is the key to successful application of the process. Because casting design affects solidification rate, the design also affects the properties that can be obtained and the discontinuities that can arise from the process. Close cooperation between designer and foundry is essential to realize the benefits of the process.

Today's technology, both in component design and manufacturing process design, makes extensive use of computer simulation for optimization. In the future, the combination of these technologies will enable designers and metal casters to produce highly engineered cast components.

Design for Deformation Processes

B. Lynn Ferguson, Deformation Control Technology, Inc.

Introduction

DEFORMATION PROCESSING involves changing the shape of a workpiece by plastic deformation through application of compressive forces. In practice, deformation processes are used to transform an initial material form (for example, cast ingot, continuously cast slab or billet, or powder) into an intermediate form (for example, plate, strip, bar, or porous preform) and then into a part. In addition to the workpiece, two tools are therefore required: a machine to generate the force and an anvil or die to support the workpiece as the force is applied. In its most primitive form, the blacksmith

applied the force through a hammer blow and the workpiece rested on the anvil as the force was applied. In its modern implementation, a machine has replaced the blacksmith, and the anvil has been incorporated into the machine as a replaceable tool component to control the shape change of the workpiece.

The goal of a deformation process is the same as other manufacturing processes in that a desired geometrical form composed of a particular material that possesses certain mechanical and/or physical characteristics must be achieved at a minimum cost. Because a product form may be produced by a wide variety of methods (as described in the article "Manufacturing Processes and Their Selection" in this Volume), what characteristics of deformation processing provide the bases for the designer to select a deformation process as the desired production method? In other words, what are the advantages that controlled plastic deformation impart to a workpiece as opposed to achieving the shape by solidification, molding of powder, or by machining? This article introduces reasons behind the selection of a deformation process as the method of choice for producing a part or product form. Some fundamental aspects of plastic flow are presented since it is the ability of a material to flow plastically that allows these processes to be used. Because machinery and tooling must be involved to impart shape change of the workpiece, it is necessary to consider the effect of friction at the tool/workpiece interface, as well as the ability of the tool to withstand the loads and temperatures required to deform the workpiece into the desired geometry. For a more complete discussion of equipment used for deformation processes, see Ref 1, 2, 3, and 4.

Design for Deformation Processes

B. Lynn Ferguson, Deformation Control Technology, Inc.

Why Use a Deformation Process?

Cost, dimensions and tolerances, surface finish, throughput, available equipment, and part performance requirements dictate the material and process selection for production. The simplest practice should be used that achieves the desired product form. Deformation offers many advantages, especially in terms of microstructural benefits, but these processes also have disadvantages, the main ones being the cost of equipment and tooling.

Advantages and Disadvantages of Deformation Processes. Discussions of process advantages must be approached carefully because most final parts are generally subjected to more than one type of manufacturing process. For example, a screw-machined part has been first cast, hot rolled to bar stock, and possibly cold rolled or drawn prior to screw machining. A forging may have been cast, hot rolled to bar form, cropped into a billet, forged through multiple stations, and then finish machined. There are steps needed to produce the starting material (ingot or cast shape), intermediate steps needed to shape the material into a manageable interim form (bar, plate, tube, sheet, wire), and then steps needed to make the final part. Both processes to make interim product forms or stock and processes to make parts are included here.

The objective of hot forging or hot rolling of cast materials is to refine the structure that results from solidification. To alter the inhomogeneous structure due to solidification and to produce a more workable microstructure, cast ingots and continuously cast slabs and blooms are typically hot worked into interim product forms, that is, plate, bars, tubes, or sheet. Large deformation in combination with heat is very effective for refining the microstructure of a metal, breaking up macrosegregation patterns, collapsing and sealing porosity, and refining the grain size.

Many design decisions are required in order to take advantage of the benefits of deformation processing while avoiding potential problems of flow-related defects: fracture or poor microstructure. Some of the advantages of a part produced by deformation are listed in Table 1. In addition, the process can be tailored to achieve tight control of dimensions for mass production, and typically some net surfaces can be achieved. While the goal is to achieve a net shape, it is rare that a totally net shape is produced by bulk-deformation processes, and some machining is typical to produce a usable part. Sheet-forming processes, however, often result in net functional surfaces. The production rate for many deformation processes can be high, so that high-volume production requirements can be met with efficient machinery utilization.

Table 1 Advantages of deformation processing

- **Improved internal quality due to compressive deformation**
  - Uniform grain structure
  - Elimination of casting porosity
  - Breakup of macrosegregation patterns
- **Beneficial grain-flow pattern for improved part performance**
  - Improved toughness due to grain flow and fibering
  - Improved fatigue resistance due to grain-flow pattern
- **Controlled surface quality**
  - Burnished surface can have improved fatigue resistance due to quality of as-forged surface
- **High throughput due to potentially high rates of forming**
- **Ability to produce a net-shape or near-net-shape part**

Disadvantages of deformation processes are listed in Table 2. It is interesting to note that many of the advantages of deformation also show up on the list of disadvantages. If the deformation process is poorly designed and/or poorly executed, the sought-after advantages will not be realized, and instead an inferior part will be produced. The categorization in Table 2 is somewhat arbitrary because metal flow, fracture, die wear, and tool stresses are so interlinked. The decisions that the designer must make concerning the preform or initial workpiece geometry, the deformation temperature, amount of force and forging speed, the friction conditions, and the metallurgical condition of the workpiece are all interrelated. Decisions about the deformation process must be made to accentuate the advantages listed in Table 1 and to overcome or avoid disadvantages listed in Table 2. Some of these design decisions are listed in Table 3.

Table 2 Potential disadvantages of deformation processing

- **Fracture-related problems**
  - Internal bursts or chevron cracks
  - Cracks on free surfaces
  - Cracks on die contacted surfaces
- **Metal-flow-related problems**

- End grain and poor surface performance
- Inhomogeneous grain size
- Shear bands and locally weakened structures
- Cold shuts, folds, and laps
- Flow-through defect

- **Control, material selection, and utilization problems**
  - Underfill, part distortion, and poor dimensional control
  - Tool overload and breakage
  - Excessive tool wear
  - High initial investment due to equipment cost
  - Poor material utilization and high scrap loss

Table 3 Design decisions associated with deformation processes

- **Part-related decisions**
  - Part or product material selection
  - Geometry and dimensions to be produced
  - Required properties (mechanical, physical, and metallurgical)
- **Process-related decisions**
  - Equipment selection (type, rate, and load requirements)
  - Starting material geometry (plate, bar, sheet, etc.)
  - Workpiece temperature and tooling temperature
  - Orientation of part during deformation step(s)
  - Location of flash or scrap loss
  - Number of deformation steps
  - Lubrication and method of application
  - Starting microstructure and control of microstructure during forging sequence (preheat practic and intermediate heating steps, if any)

B. Lynn Ferguson, Deformation Control Technology, Inc.

Categories of Deformation Processes

Dieter (Ref 5) has categorized deformation processes into five broad classes:

- *Direct Compression Processes:* Force is applied directly to the surface of the workpiece and material flow is normal to the application of the compressive force; examples are open-die forging and rolling.
- *Indirect Compression Processes:* Deformation is imposed by compressive loads generated as the workpiece is pushed or pulled through a converging die. The direction of the external load applied to the workpiece is in the direction of workpiece motion; examples include extrusion, wire drawing, and deep drawing.
- *Tension-Based Processes:* Tensile loading is developed in the workpiece to cause thinning, with stretch forming being a primary example.
- *Bending Processes:* A bending moment is applied to cause a geometry change, the deformation being limited to the local region of the bend. Sheet bending, rod bending and coiling, and plate bending are example processes.
- *Shearing Processes:* Metal deformation is highly localized in a workpiece as offset blades moving in opposite directions generate a plane of intense shear to intentionally cause a shear failure. Hole punching, plate shearing, blanking, and slitting are examples of shearing processes.

Other terminology is also recognized in the industry. *Bulk-forming processes* are processes that have large volumes of material participating in the deformation and may be termed three-dimensional processes. A typical goal is to alter a cast grain structure to a more uniform, sound structure, with hot rolling if ingots, slabs, or billets being a primary example. Table 2 in the article "Manufacturing Processes and Their Selection" in this Volume is a list of some general characteristics of bulk-deformation processes such as hot forging, hot extrusion, cold forging, cold extrusion, wire and strip drawing, and rolling. The remaining deformation processes are defined by an initially large surface-area-to-volume ratio such that the volume of material in the deformation zone at any given time during the process is small. *Sheet-forming processes*--blanking, shearing, bending, spinning, and stretching--fall into this category (see Table 3 in the article "Manufacturing Processes and Their Selection").

Another general way of referring to deformation processes are as hot-, warm-, or cold-working processes. Cold working typically refers to processes that are conducted at or near room temperature. Hot-working processes are conducted at temperatures above the recrystallization temperature, which is roughly a homologous temperature of 0.5. Homologous temperature is the ratio of workpiece temperature to its absolute melting point. Warm working processes are conducted at intermediate temperatures. These designations really relate to the deformation mechanisms involved in plastic flow and the effect that the working operation has on the grain structure. Hot working produces a recrystallized grain structure, while the grain structure due to cold working is unrecrystallized and retains the effects of the working operation.

Fundamentals of Deformation Processing

There are four major design considerations in applying a deformation process. The first consideration is the workpiece material and its flow stress behavior. The second consideration is the fracture behavior of the material and the effects of temperature, stress state, and strain rate on fracture; this combined view of ductility and stress state is termed workability for bulk-forming processes and formability for sheet-forming processes. The third major consideration is a determination of the desired final microstructure needed to produce an acceptable product and a determination of which process should be used to produce this microstructure. A fourth consideration involves added constraints of available equipment and economics in addition to flow stress, forming, and part performance considerations. The fourth consideration usually dominates the other considerations, sometimes to the detriment of the material being worked.

Historically, deformation processing has fallen in the gap between the traditional disciplines of metallurgy and mechanics, and, as a result, this area has often been neglected in an academic sense. A main reason for this is the difference in length scales by which mechanics and materials science view a material. The length scale of deformation is at the atomic level, and it is at this level that materials science addresses deformation. In manufacturing, deformation effects are related or measured at a macroscopic level, and continuum mechanics is applied to analyze and explain plasticity quantitatively. However, to understand the macroscopic response of materials to temperatures and rates of deformation, consideration must be at a lower length scale level, at least to qualitatively explain material behavior. The empirical equations used to address plasticity do not generally capture the microscopic aspects of deformation. Fortunately, the metals that are commonly processed by bulk-deformation methods have many grains per unit volume, and microscopic events are suitably averaged at the macroscopic level. The macroscopic or continuum mechanics approach begins to break down when the grain size approaches the physical size of the workpiece or when a dominant crystallographic texture is present in a workpiece. Examples of the former include fine wire drawing, bending of fine wire, and sheet-forming processes. Primary examples of the latter are sheet-metal-forming processes or bending of heavily drawn wire where crystallographic texture plays a dominant role. An additional complication is the fact that most metals have more than one phase present in their microstructure. The second phase may be present due to alloying, that is, cementite in iron, or it may be an unwanted phase, that is, sulfide or silicate inclusions in steel. The effects of these second phases are again averaged at the macroscopic level, and the material has not been adequatelly described as having separate phases from a mathematical sense. The materials science community and the mechanics community are trying very hard to bridge this length scale problem, but for now the most useful analysis tools are combinations of continuum mechanics and empirical results.

B. Lynn Ferguson, Deformation Control Technology, Inc.

Flow Stress

Flow stress behavior refers to the effects of temperature, deformation rate, and work-hardening behavior on the stress needed to cause further plastic deformation. Flow stress characterizes the dynamic stress-strain behavior of a material, where

$$\sigma_f = f(\varepsilon, \dot{\varepsilon}, T, M, G)$$

where σ_f is flow stress, ε is the local strain level, $\dot{\varepsilon}$ is the local strain rate, T is the local temperature, M is the microstructure in terms of phases and distributions of phases, and G is grain size.

The stress-strain curves for commercially pure aluminum over a range of temperatures and at two strain rates are given in Fig. 1. These curves show that at low temperatures work hardening is pronounced as flow stress increases rapidly with

strain. At high temperatures, there is negligible change in flow stress with strain. To better examine strain rate effects, Fig. 2 shows a plot of stress at 0.2% strain versus strain rate data for 6063-O aluminum plotted on a log-log scale. Strain rate is the time dependence of strain, $\dot{\varepsilon} = d\varepsilon/dt$. As temperature increases, the flow stress decreases, and furthermore, the increase in slope of these lines with temperature shows that strain rate becomes more influential at higher temperatures. Laboratory tests such as the compression test and tensile test have been developed to measure flow stress, and atlases of flow stress data are available (Ref 1, 3, 4, 5, 8, 9). Typically, the data are reported for a constant temperature and constant strain rate, and these data are vital for numerical calculations regarding deformation processes. However, care must be exercised when applying these data to a specific problem because the grain size, second-phase volume fraction, and the distribution of second phases may be different for a specific case. For this reason, the pedigree of any data that are used for any numerical calculations is necessary information.

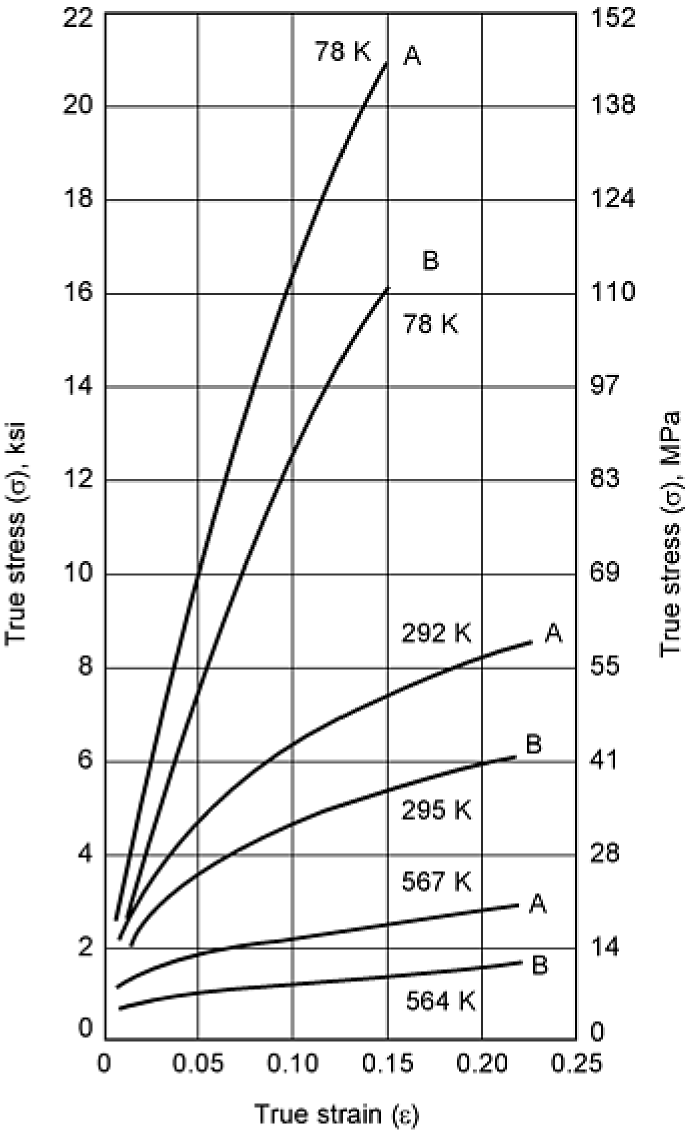

Fig. 1 True stress-true strain curves for commercial-purity aluminum as a function of temperature and strain rate. Strain rates: A, 0.167/s, B, 0.00194/s. Source: Ref 6

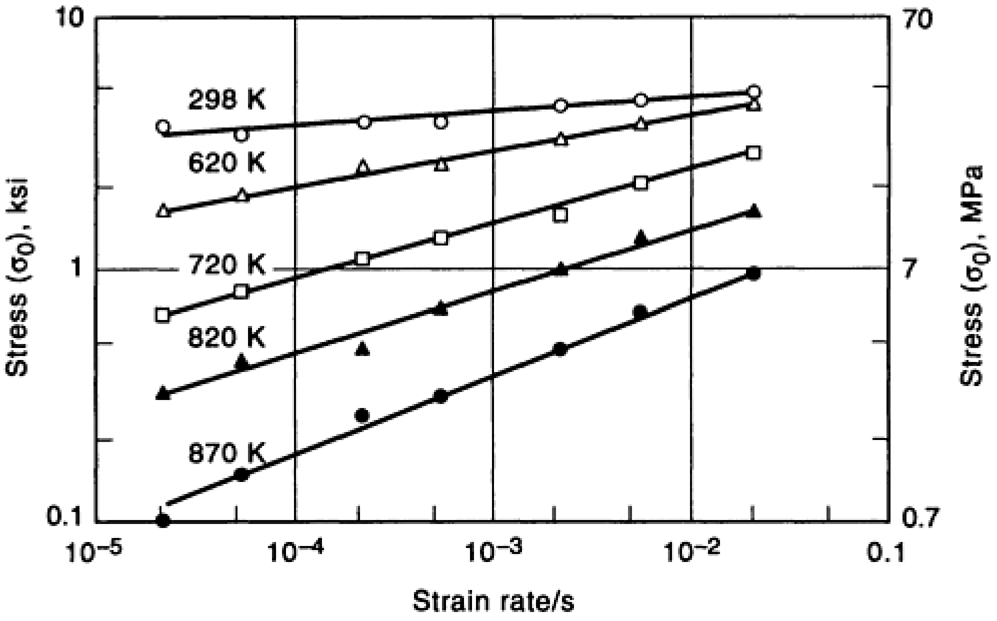

Fig. 2 Flow stress for 6063-O temper aluminum at a strain of 0.2%. Source: Ref 7

Dislocations, or defects in the crystal structure, enable ductile behavior of metals as these defects participate actively in deformation at the microscopic level. For polycrystalline metals, there is a difference in ease of deformation between grain interiors and grain boundaries. The equicohesive temperature is the temperature at which the grain interiors and the grain boundaries have the same strength or resistance to deformation. This temperature is not a fixed temperature, but is sensitive to the rate of stress application. A second temperature of significance is the homologous temperature, which is the ratio of temperature to the absolute melting point. The sections that follow address deformation process temperature effects.

Cold Working

Cold working results in a deformed, unrecrystallized grain structure with the grains being elongated in the direction of metal flow. Deformation begins in the grain interiors first when the critical resolved shear stress of the material is exceeded. At cold-working temperatures, the grain boundaries are more resistant to deformation, so workpieces with fine grains and a large amount of grain boundary area are stronger than coarse-grained material of the same alloy. This dependence of yield strength on grain size and the amount of grain-boundary area in a material is captured by the well-known Hall-Petch equation:

$$\sigma_y = \sigma_i + k/\sqrt{D} \quad \textbf{(Eq 1)}$$

where σ_y is the yield stress of polycrystalline metal, σ_i is the stress related to resistance of dislocation motion within a grain, k is the parameter relating-grain-boundary hardening effect, and D is the average grain diameter. Equation 1 indicates that the yield strength of an alloy increases as the grain size becomes finer, where yield strength is the initial flow stress.

Once deformation is initiated, the moving dislocations interact with each other and with the grain boundaries to make continued yielding more difficult. This is work hardening, and a further feature of cold forming is that work hardening effects continue to build with continued deformation. An empirical relationship for cold working between flow stress and plastic strain is:

$$\sigma_f = K \cdot \varepsilon^n \quad \textbf{(Eq 2)}$$

where σ_f is the flow stress, K is the strength coefficient (stress when ε= 1.0), $\varepsilon$is the plastic strain, and n is the work-hardening exponent. From Eq 2, a high-strength coefficient indicates a high initial resistance to plastic flow. Metals with a high K require large machines for deformation. Work hardening is a measure of how the resistance to plastic flow increases as the metal is deformed. Typically, n has values of 0.1 to 0.5 for cold working, with 0 being a perfectly plastic metal (no work hardening). A metal with a high work-hardening exponent but a low strength coefficient will achieve a high strength level after a large amount of deformation. Copper, brasses, and low-carbon steels are typical examples of metals that are cold worked to produce improved hardness and strength in the formed part. Table 4 contains some values of K and n for these metals (Ref 5). For steels, K increases with carbon content, while n generally decreases. Both copper and brass have a much higher work hardening exponent than steel. Both K and n are affected not only by chemistry, but also by prior history and the microstructure. This is shown in Fig. 3 for the work-hardening exponent for a variety of steels and microstructures.

Table 4 Values for the work-hardening exponent and strength coefficient for selected metals

Metal	Condition	Work-hardening exponent (n)	Strength coefficient (K)	
			MPa	**ksi**
0.05% C steel	Annealed	0.26	531	77
4340 steel	Annealed	0.15	641	93
0.6% C steel	Quenched and tempered 540 °C (1000 °F)	0.10	1572	228
0.6% C steel	Quenched and tempered 700 °C (1300 °F)	0.19	1227	178
Copper	Annealed	0.54	317	46
70/30 brass	Annealed	0.49	896	130

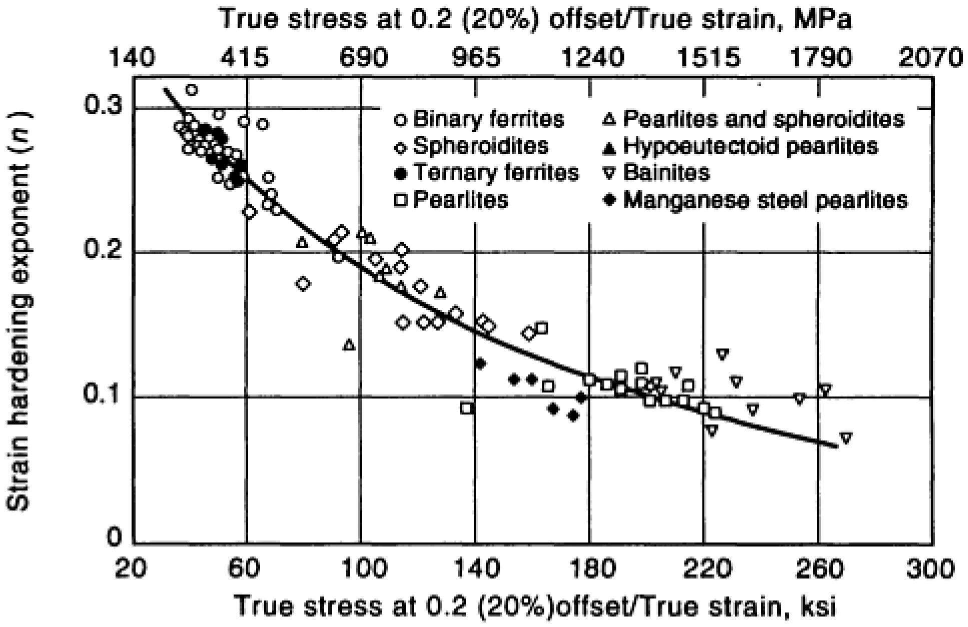

Fig. 3 Relationship between yield strength and the strain-hardening exponent (*n*) for a variety of steel microstructures. Source: Ref 10

The work-hardening exponent indicates further information about the metal. Figure 4 shows an ideal tensile stress versus strain curve for cold deformation. The work-hardening exponent corresponds to the strain at which strain becomes localized and results in necking. The higher the value of *n*, the greater the strain before necking begins. This is especially important for metals undergoing deformation processes that are tensile in nature, such as many sheet-forming processes and wire drawing.

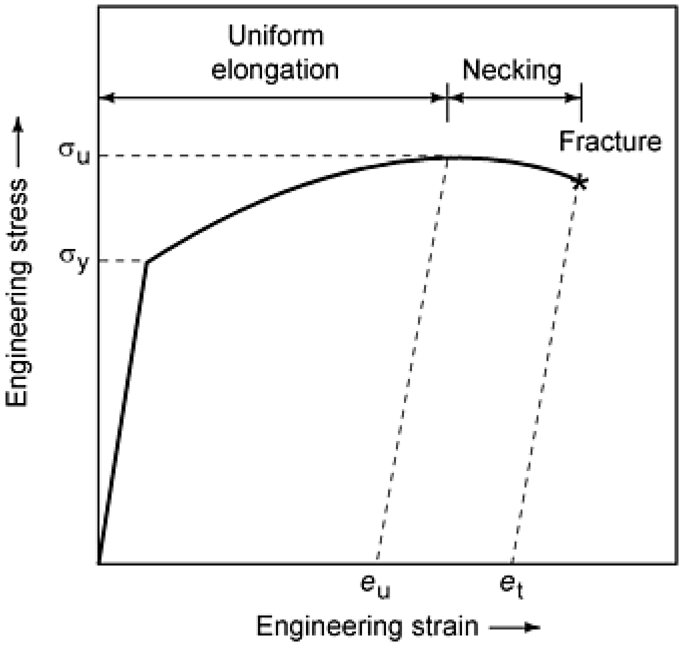

Fig. 4 Schematic engineering tensile stress-strain curve to show uniform elongation, ultimate strength, and necking. e_t, tensile elongation; e_u, uniform elongation; σ_u, ultimate tensile strength; σ_y, yield strength

Over the range of strain rates at which cold-deformation processes are conducted (0.1 to 100/s), the sensitivity to strain rate for most metals is low, as supported by the low slopes at low temperatures in Fig. 2. Strain level rather than strain rate controls the flow stress, in addition to the initial strength coefficient *K*.

Grain growth is not a factor in cold working. However, grain flow and a change in grain aspect ratio is very much a factor. As the grains distort, a well-defined grain-flow pattern is developed due to grain-boundary alignment. Nonmetallic inclusions may also participate and further define a definite directionality in the microstructure and mechanical properties due to this mechanical fibering. Extremely deformed microstructures, as are present in cold-rolled sheet products, may also show alignment of crystallographic planes or texture, as well as grain-boundary alignment. The result is anisotropic behavior of the deformed material, either in service or in subsequent deformation steps. The designer must be aware of the effects of microstructural features such as fibering or preferred orientation on mechanical properties, and the relationship of microstructural alignment and performance stresses. This is especially critical in cases where fatigue and fracture toughness are design issues.

Design for Deformation Processes

B. Lynn Ferguson, Deformation Control Technology, Inc.

Hot Working

Hot working takes place roughly above a homologous temperature of 0.5, with typical hot-working temperatures being 70 to 80% of the absolute melting temperature. At these temperatures, there is a high amount of internal energy available and a number of deformation mechanisms, in addition to slip, are available. These additional mechanisms include power law creep mechanisms such as dislocation glide and climb, and diffusional flow such as diffusion of vacancies and boundary motions. Referring again to Fig. 1, the room-temperature curves for aluminum show typical work-hardening behavior associated with cold deformation. However, at high temperature work hardening is low and the flow stress curve becomes very different from that of cold deformation. Hot working involves recovery and recrystallization of the microstructure. These may be dynamic or static in nature, with dynamic recovery and dynamic recrystallization occurring during the deformation step, and with static recovery and recrystallization occurring after the deformation step while the workpiece is still hot.

Figure 5 shows schematically grain structure changes during hot rolling to a moderate level and deformation and extrusion with a high level of deformation (Ref 3). Stacking-fault energy, as mentioned in Fig. 5 as being high or low, relates to the dislocation structure of the crystal. Low stacking-fault energy results in wide stacking faults that have a relatively high resistance to thermally activated mechanisms, and these metals strain harden rapidly. Metals with high stacking-fault energy have narrower stacking faults, the dislocations are more mobile, and as a result the rate of work hardening is low. In comparing the effect of hot deformation in metals having low or high stacking-fault energies, Fig. 5 shows that dynamic recovery occurs in all cases. However, a high deformation level is required to produce recrystallization in metals with high stacking-fault energy, while metals with low stacking-fault energy can recrystallize at a lower level of deformation. Metals with low stacking-fault energies include brass and austenitic stainless steels, and metals having high stacking-fault energy include aluminum and nickel alloys. In practice, most conventional hot-working processes are too fast for dynamic recrystallization to occur.

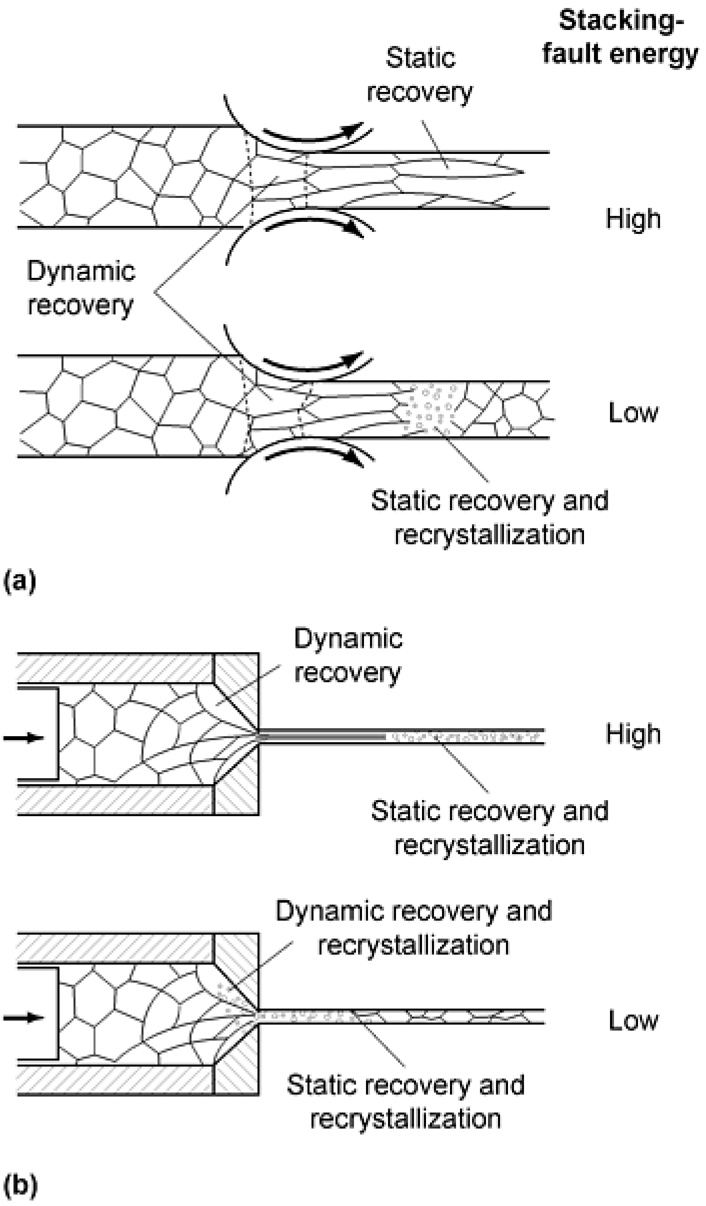

Fig. 5 Hot-working effects on microstructure. (a) Rolling with a thickness strain of 50%. (b) Extrusion with a strain of 99%. Source: after Ref 3

Dynamic recovery occurs when there is sufficient atomic mobility to balance or nearly balance work hardening. That is, dislocations are sufficiently active to move in response to local stresses associated with dislocation tangles and forests, the presence of second phases, and other local stress concentrations. A metal that is undergoing dynamic recovery during hot working will exhibit negligible work hardening, with most low-carbon and low-alloy steels being primary examples. Figure 6(a) shows a schematic flow stress-strain curve for a metal that dynamically recovers during hot working (Ref 3).

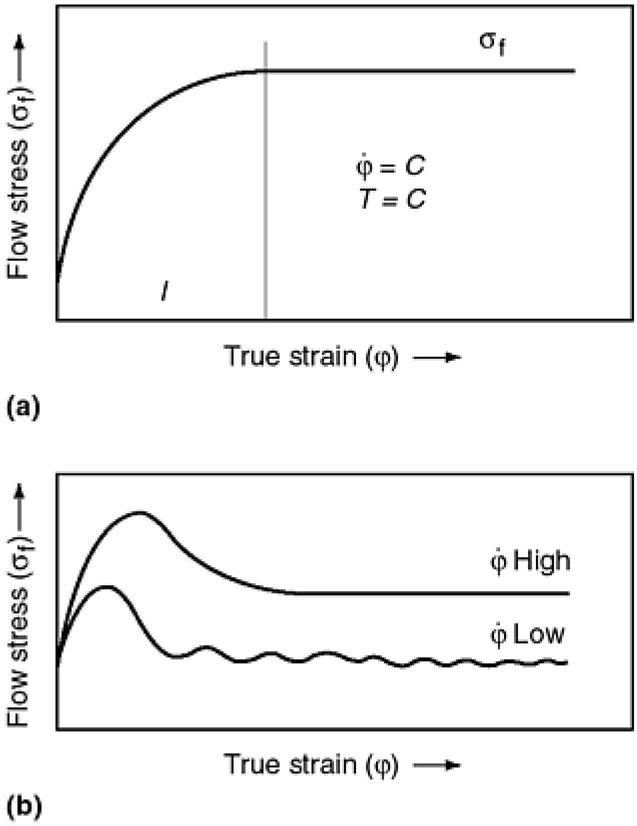

Fig. 6 Schematic flow stress curves representative of (a) dynamic recovery during hot working and (b) dynamic recovery and dynamic recrystallization. $\dot{\varphi}$, shear strain rate; *T*, temperature; *C*, constant. Source: Ref 3

Recrystallization occurs if a critical level of strain energy is achieved so that a new set of grains forms. If recrystallization occurs during hot deformation, the result is flow softening as shown in Fig. 6(b) (Ref 3). Examples of metals that may flow soften during hot working include nickel-aluminum bronze, commercial purity titanium, super α_2 titanium aluminide, Ti-6Al-4V, and 7075 aluminum. Whether or not recrystallization and flow softening occurs is a function of the working temperature and strain rate and the local deformation level. Flow softening can lead to strain localization and highly nonuniform microstructures, and in extreme cases, shear cracking. This is mainly true in cases where this phenomenon occurs over a narrow range of temperatures or strain rates.

Recovery and recrystallization are thermally activated, and therefore these mechanisms are very dependent on temperature. They are also very dependent on the level of deformation because strain is indicative of a growing volume fraction of defects in the crystal structure and greater internal energy or stress within the grains. The benefit of recovery is that work-hardening effects can be minimized by allowing atomic rearrangement to reduce the internal stress within the grain. This is why hot-working processes can accomplish large deformation levels while maintaining relatively low working loads. For processes such as hot rolling, extrusion, and forging, the time in the deformation zone is short. Grain refinement is accomplished by static recrystallization after hot working. A high level of hot deformation followed by a hold time at an elevated temperature causes static recovery and recrystallization to result in a fine grain size. This may occur in hot rolling, where there is time between roll passes, or after hot forging where the workpiece slowly cools in a bin. Metallurgical specifications are more frequently including grain size limits, and therefore it is becoming more critical to control workpiece temperature, deformation rate, the amount of deformation per working step, and the time between steps in order to control the microstructure of the deformed workpiece.

The other microstructural phenomenon that can occur during hot-working processes is grain growth. The natural drive for a polycrystalline material is to minimize internal energy, and because grain boundaries are regions of higher internal energy, grain growth is a way for nature to minimize energy by minimizing the grain-boundary content. Grain growth is also thermally driven, and because hot-working processes may hold a workpiece at a high temperature for a long time, grain growth can occur. In fact, in an extended hot working process such as ingot break-down rolling, a cyclic history of grain deformation, recrystallization and growth is established for each deformation step. The ability to put work into the

grains at a level sufficient to cause recrystallization is the reason that fine grains can be developed from a coarse-grained structure by hot working. Hot-working processes must balance recovery and recrystallization against grain growth in order to be effective in refining large-grained microstructures or in homogenizing microstructures of mixed grain sizes. For the designer, this is important because grain size has such a pronounced effect on mechanical performance of the part.

At temperatures above the equicohesive temperature, the grain interiors are more resistant to deformation than the grain boundaries, and the grain boundaries can sustain deformation. If a very fine grain size can be achieved and maintained during deformation at a low strain rate, grain-boundary sliding can occur. This mechanism, in combination with other thermally activated deformation mechanisms, is used successfully to deform very-fine-grained metals to large deformation levels, and this is termed superplastic behavior. Superplastic behavior is not a primary feature in most hot-working processes because of the required low deformation rates and extremely fine grain size. Creep forming, hot-die forging, isothermal forging and sizing, and isothermal rolling are processes that rely in part on grain-boundary sliding and other thermally activated deformation mechanisms.

Some general observations concerning recovery, recrystallization, and grain growth include:

- If the metal has been previously deformed, grain growth is preceded by recovery and by recrystallization.
- The driving force for recrystallization exceeds that of grain growth, thus recrystallization can occur at lower temperatures than grain growth.
- If the workpiece is stress free, grain growth begins without recovery or recrystallization occurring, but the temperature must be relatively high.
- The rate of grain growth is a function of the starting grain size, grain shape, and, most importantly, temperature. The driving force for grain growth is the minimization of internal energy, with the amount of grain-boundary area representing internal energy. Therefore, a fine-grained workpiece will experience a higher rate of grain growth than a coarse-grained workpiece at the same temperature.
- As the workpiece is held at temperature, a saturation grain size will be reached, and holding the workpiece for a longer time will not result in further appreciable grain growth.
- Grain growth is retarded by the presence of stable second-phase particles, as these tend to hinder grain-boundary movement. Aluminum-killed steels have finer grain size than nonkilled steels because of the presence of AlN precipitates that lock up grain boundaries. Other common second phases that can be used to control grain size in iron and other metals include thermally and chemically stable carbides, nitrides, and oxides.

Design for Deformation Processes

B. Lynn Ferguson, Deformation Control Technology, Inc.

Workability

Workability is a measure of the ability of a metal to endure deformation without cracking. This term is applied to bulk-forming processes such as forging, rolling, extrusion, and bending of thick sections. Ductility as measured by the tensile test is a good way to compare the inherent resistance of different materials or different microstructures for the same material. However, ductility alone is insufficient when judging fracture susceptibility of a deformation process because of fracture dependence on both the local strain and stress states. Workability is not a well-defined, specific property like tensile reduction of area at fracture, but rather it must be defined in combination with the stress state that a particular deformation process imposes on the material. Some common cracking modes are discussed below. (Workability is also

discussed in the articles "Relationship between Materials Selection and Processing" and "Manufacturing Processes and Their Selection" in this Volume.)

Free-Surface Cracking

Cracking can occur on a free surface as it expands due to the deformation process. For forging processes, this would include cracking on the exposed surfaces during upsetting and cracking on surfaces at the leading edge of localized extrusion during forging. For rolling processes, this may be edge cracking of rolled slabs, plates, or rings. Figure 7 shows that free-surface cracking occurs in bending, upset compression of cylinders, and rolling. Uniaxial compression tests are used to construct workability limits that may then be used for evaluating other deformation processes that may suffer from cracking on free surfaces (Ref 11).

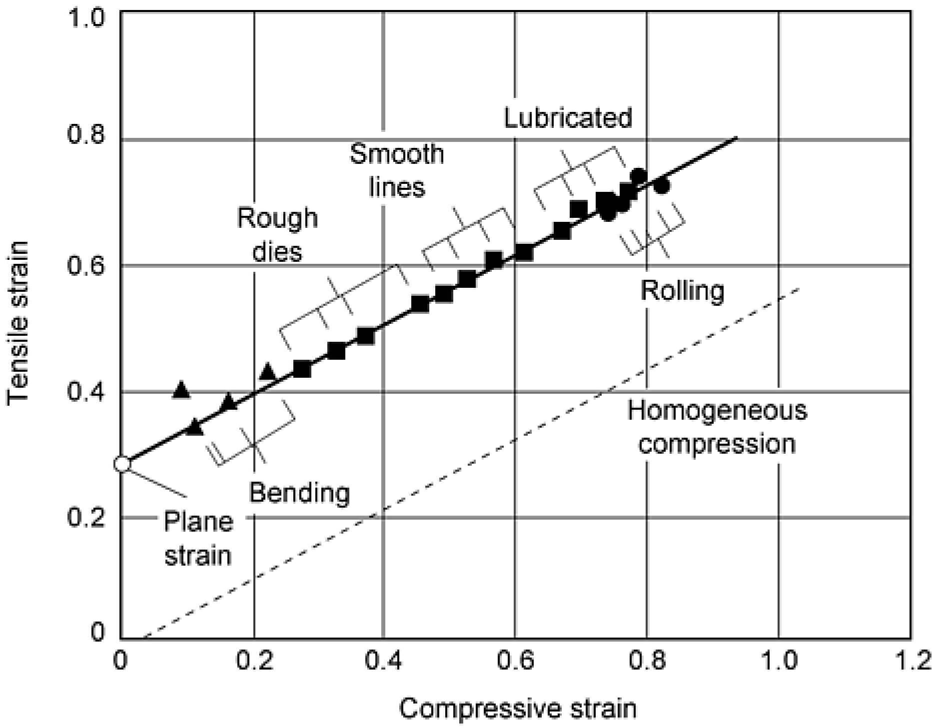

Fig. 7 Workability limit for upsetting, bending, and rolling with varying aspect ratios and friction conditions. Source: Ref 11

Experiments have shown that the strain state developed on the free surface of a workpiece during deformation dictates the overall level of deformation that may be achieved before a surface crack occurs (Ref 8). The strain path that is experienced at a free surface is a function of friction and deformation-zone geometry, which for upsetting is the workpiece aspect ratio (height/diameter). This effect is shown in Fig. 8, where a steeper strain path is observed for either higher friction or lower workpiece aspect ratio. Figures 7 and 8 in combination indicate that for a given material and set of process conditions (temperature and strain rate), a forming limit can be defined by the set of fracture points for various strain paths. The slope of this forming limit is approximately -0.5 in major-minor strain space. Different metals have different workability limits, as shown by comparing 1020 steel and 303 stainless steel in Fig. 9. These limits change with chemistry, grain size, temperature, second-phase content, and possibly with strain rate.

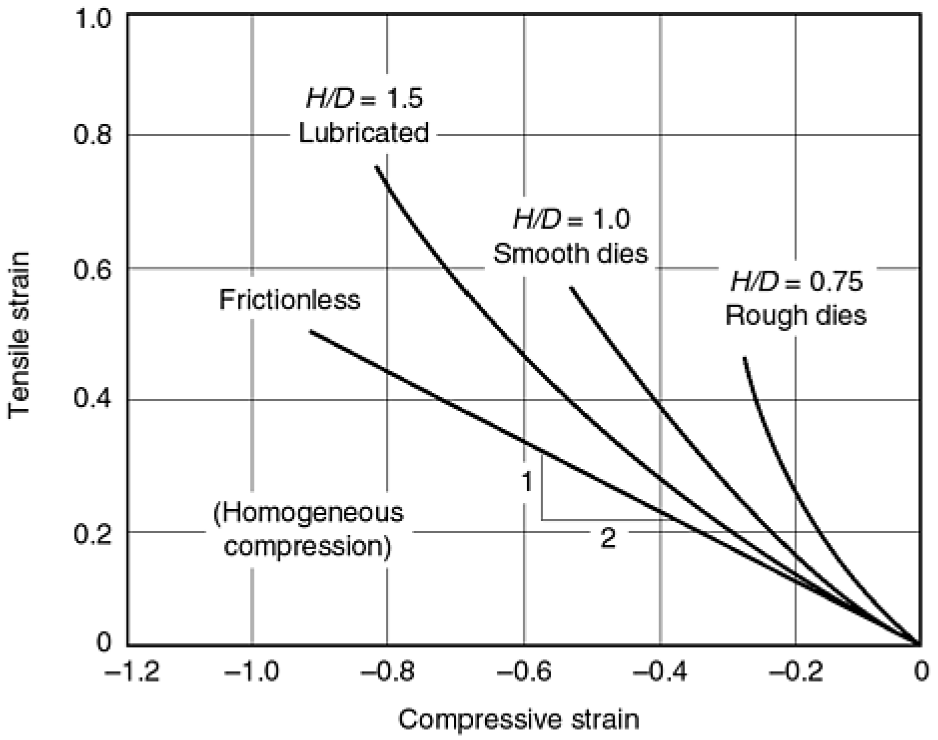

Fig. 8 Surface strain paths observed in upset tests for different friction conditions and aspect (height/depth, or *H/D*) ratios. Source: Ref 11

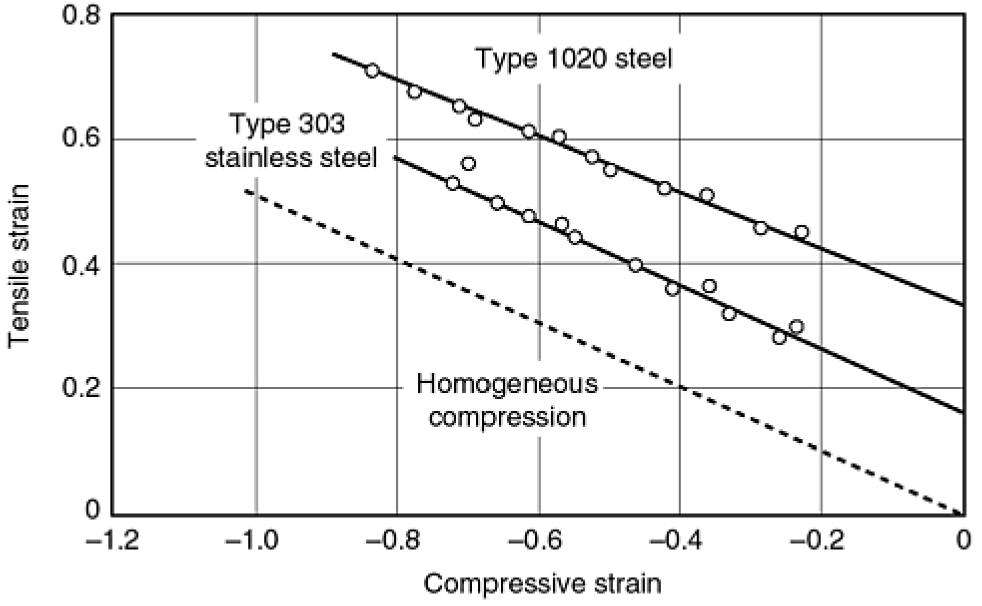

Fig. 9 Workability limits for free-surface fracture for 1020 steel bar and 303 stainless steel bar at room temperature. Source: Ref 11

The concept of a forming limit for free-surface fracture is important because the workability of a metal may be characterized for a particular set of process conditions. In general, as the working temperature is increased, the location of the fracture line will move upward, indicating that higher deformation can be accommodated before fracture. Figure 10 shows the improvement in workability with temperature for sintered preforms for powder forging (Ref 12). Figure 11 shows that higher temperatures are not always beneficial and that, for IN718, a nickel-base superalloy, a temperature limit

of about 1120 °C (2050 °F) for hot working exists (Ref 13). Experimental observations have shown that the slope of the line increases with strain rate for some metals, most notably some brasses and austenitic stainless steels (Ref 14).

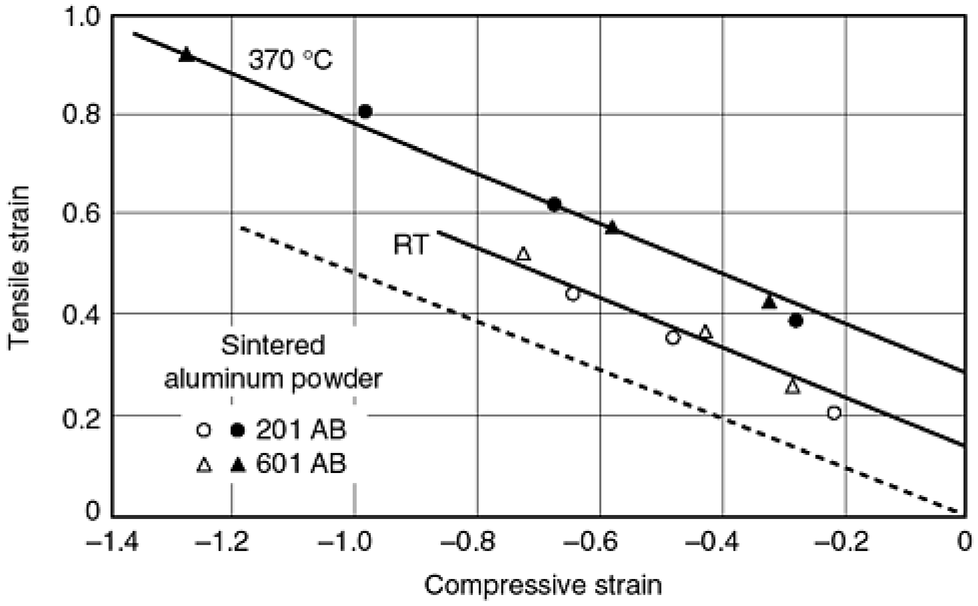

Fig. 10 Workability limits for sintered aluminum alloys at room temperature and at 370 °C (700 °F). Source: Ref 12

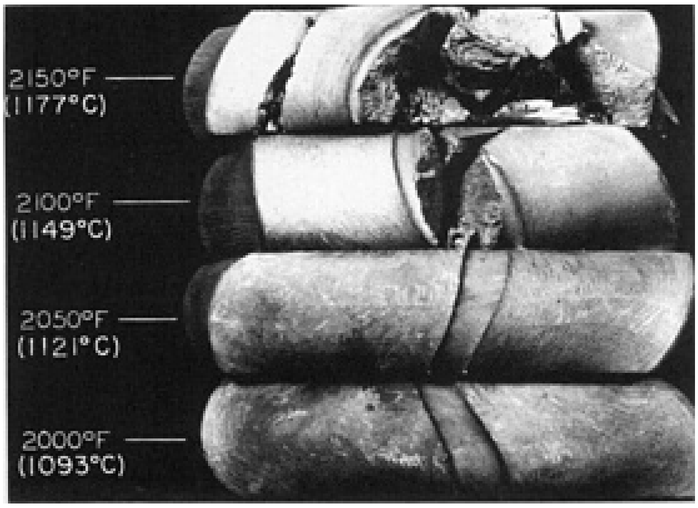

Fig. 11 Notched bar upset testpieces for IN718 showing the workability sensitivity to deformation temperature. Source: Ref 13

Experiments have also shown that the position of the line drops (lower formability) as the second-phase content increases, much like the tensile ductility decreases with second phase as shown in Fig. 12 (Ref 15). For example, a rolled steel bar may have a higher fraction of inclusions near its centerline (especially for conventional ingot metallurgy material). Thus, workpieces machined from the center of the bar may have reduced workability in comparison to the outer bar material. Free-machining steels with high manganese sulfide content have reduced workability in comparison to equivalent steel of normal sulfide content. The orientation of the second phases with regard to the stress state is also critical, especially for nonspherical second phases. Figure 13 shows the orientation of some bend and compression test samples sectioned from hot-rolled steel bar. Figure 14 shows the fracture lines that were experimentally determined for these samples. Tensile stresses perpendicular to the plate thickness resulted in fracture at the lowest strain values. Highest strains could be achieved in the rolling direction before free-surface cracking was observed. Process design should include an assessment

of the stress state developed during deformation and the orientation of initial mechanical fibering due to inclusions and the initial grain structure. Similarly, the performance of a part in service will be dependent on the orientation relationship between the stress state and the microstructure, including the resultant grain-flow pattern. Sintered preforms for powder forging have reduced workability in comparison to bar stock workpieces, making preform design a critical design issue for successful forging.

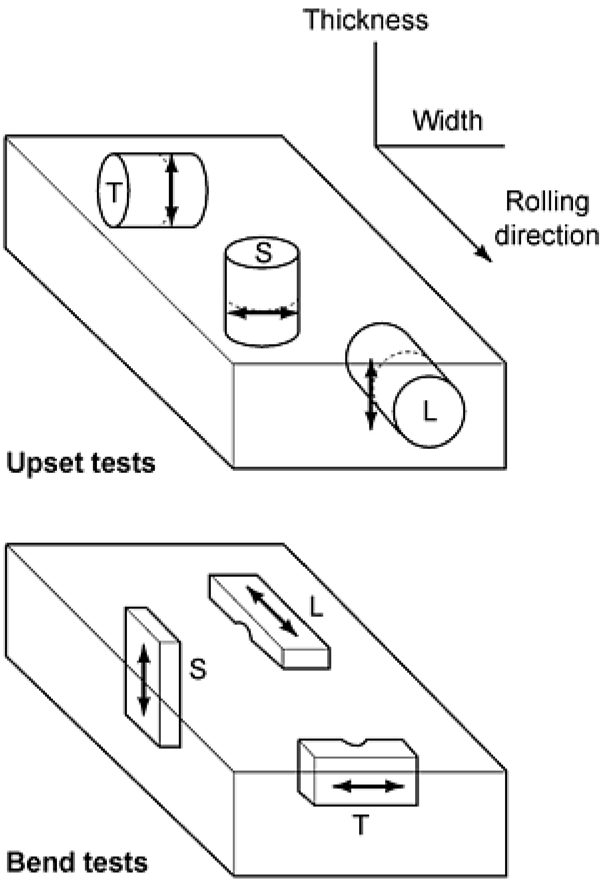

Fig. 13 Orientation of bend samples and compression samples in a rolled plate showing the relationship between tensile stress developed during testing and the original orientation in the plate. Source: Ref 16

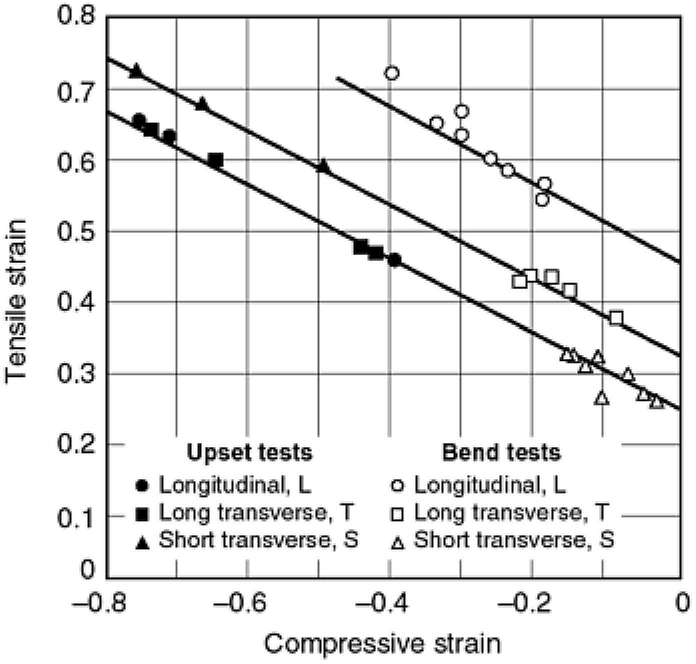

Fig. 14 Workability limits for the sample configurations shown in Fig. 13 indicating the directionality in structure developed during plate rolling. The material is 1045 hot-rolled plate. Source: Ref 16

The fracture line location is sensitive to the microstructure. For example, a spheroidized structure for a high-carbon steel has a higher fracture line position than a pearlitic microstructure, as shown by the tensile ductility improvement by spheroidization in Fig. 15 (Ref 17). This figure also shows the decrease in ductility with increasing content of second phase, carbides in this case, as was shown in Fig. 12 for a different material system.

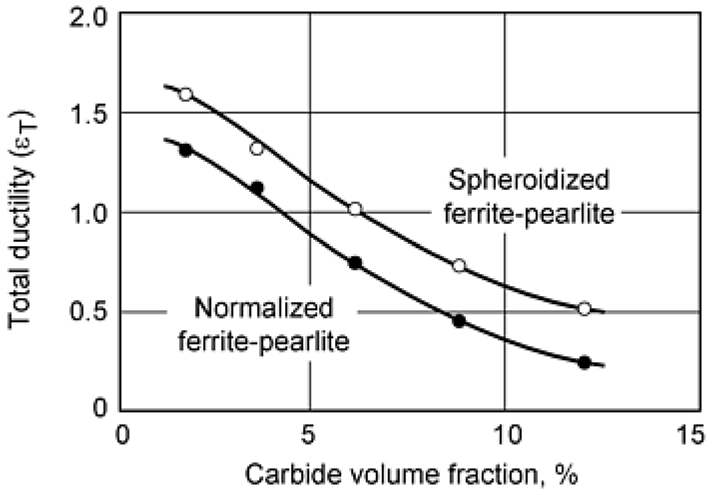

Fig. 15 Effect of carbon content and spheroidization on ductility. Source: Ref 17

The fracture line for free-surface cracking can also be used to show the benefit of hydrostatic pressure on fracture resistance, see Fig. 16 (Ref 12). This figure also shows the detrimental effect of hydrostatic tension on fracture resistance.

As an example, continuously cast slabs may be rectangular in cross section with perpendicular sides or they may have rounded corners in the thickness direction. The susceptibility to edge cracking during rolling is dependent on the geometry of the free edge. A rounded side has less vertical free pressure on it from the rolls than a straight side. Consequently, there is more compression on the straight side and edge cracking is less of a problem. Figure 17 shows thickness strains needed to produce edge cracking for cold strip rolling, and as shown, square-edged strip can endure higher reductions than round-edged strip without cracking (Ref 19). This relates directly back to the effect of hydrostatic pressure on the workability line shown in Fig. 16.

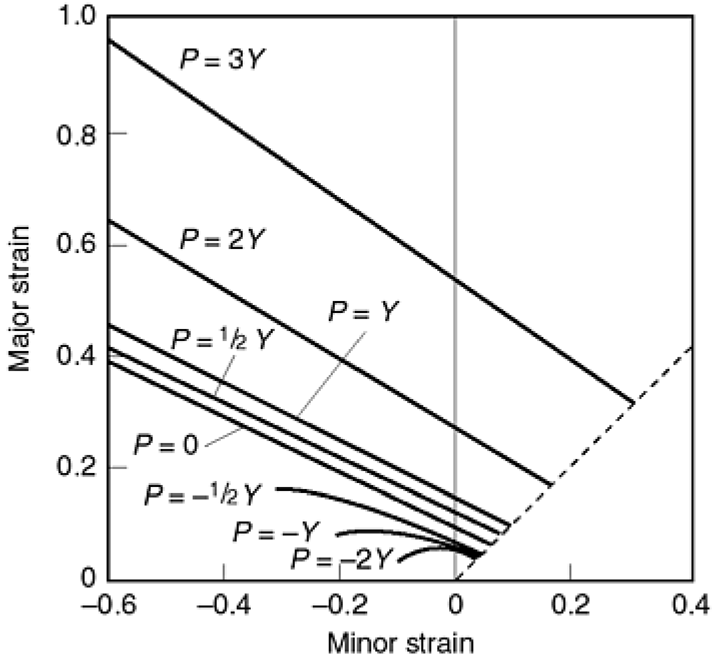

Fig. 16 Effect of hydrostatic pressure (*P*) and tension on the workability limit. *Y*, yield strength. Source: Ref 12

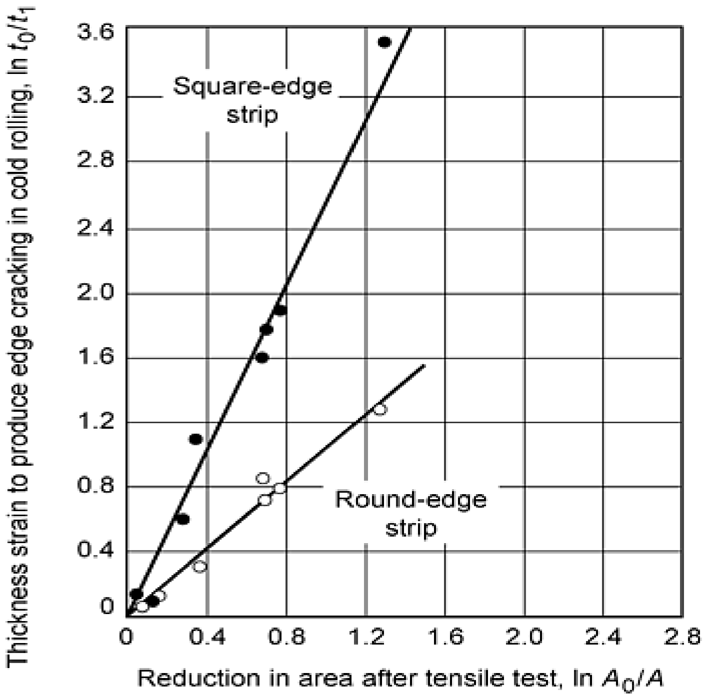

Fig. 17 Thickness strains to produce edge cracking in flat rolling versus tensile ductility. Notice the increased

rolling strains possible with the square-edged strip. Source: Ref 18

The fracture line location is not exact--its location is statistical in nature. Metals with exceptional workability may never experience free-surface fracture during conventional deformation processes. Indeed, producers of cold forgings often report that free-surface cracking is low on their list of defect problems. This is due partly to the fact that past history has already limited cold-forging processes to readily cold-forged materials. For metals with lower workability such as sintered metals, nickel-base superalloys, and oxide dispersion-strengthened alloys, the use of these diagrams can save much time and development cost in designing a process to produce parts successfully from these materials. Fracture limits are also useful in identifying forging conditions to avoid, such as inappropriate temperature ranges, strain-rate ranges, or workpiece geometries. Workability lines are also helpful in designing process sequences that may require annealing or other in-process heating steps to prevent cracking problems.

Cracking on Die Contact Surface

Cracking on surfaces in contact with a die is a common problem. These cracks usually do not propagate deeply into the workpiece, but instead result in unacceptable surface quality or unacceptable machining depths if that surface was to be finish machined. As the forging community has moved closer to net-shape forming, this type of defect has become an increasing problem. Causes of this problem include nonuniform lubrication, flow around die corners, and an improper starting workpiece surface.

Lubrication variations causes local velocity gradients and secondary tensile stresses in the plane of the flowing surface. Even though there is compression normal to the workpiece surface, the local in-plane tension may be high enough to cause cracking. Once a small crack forms, the tension is relieved so the crack does not propagate.

A typical location for this type of cracking is near a punch or die corner. Here, there is a drop in internal pressure as metal flows around a corner, and this pressure drop often results in surface cracking. Again, experimental studies have shown

that combinations of shear deformation combined with tension or low values of hydrostatic pressure in the vicinity of a die corner are responsible for surface cracking (Ref 12). Figure 18 shows cracks along a die contact surface on a rib/web forging. Figure 19(a) shows schematically the drop in hydrostatic pressure experienced by the workpiece as it flows around a die corner into a rib. The beneficial effect of hydrostatic pressure on the fracture line is also shown schematically, with position "0" being a point of high pressure in Fig. 19(b). As metal flows around the die corner (moves from point 0 to 1 to 2 to 3), it experiences a drop in hydrostatic pressure while the surface is being progressively stretched. The fracture line drops as the level of hydrostatic pressure drops, with fracture occurring when the tensile strain exceeds the fracture intercept value for this plane-strain deformation. The severity of the drop in hydrostatic pressure and the magnitude of shear strain is a function of friction, rib width, and die corner radius. Here, wide ribs are more susceptible to cracking than narrow ribs, and friction on the die wall actually helps provide back pressure to retard the die contact fractures. A draft angle on the rib also helps promote back pressure. However, both increased surface friction and draft angle generate higher tensile strains on the top of the rib and may thus promote free-surface cracking.

Central Burst (Chevron Cracking)

A central burst, or chevron crack, is a dangerous type of defect because it cannot be seen visually. On the outside, the part looks like an acceptable part, but the interior rupture will cause unacceptable part performance. A central burst is detected by x-ray or ultrasonic inspection methods.

Central bursting is most commonly associated with extrusion and drawing operations, although it can be generated by forging and rolling processes as well. Rotary piercing is possible because of centerline fracture. The cause of a burst is hydrostatic tension generated along the workpiece centerline. A change in deformation zone geometry is usually sufficient to eliminate the problem.

Figure 20 shows a series of die angles and reductions for cold drawing that produced either sound strip or strip with bursts (Ref 18). In this figure, the negative ratios indicate hydrostatic tension at the strip centerline. Figure 21 from this same study shows that die angles of 20 and 30° actually caused a density loss upon strip drawing due to porosity development along the strip centerline. At a 10° die angle there was no centerline porosity developed in the strip. From Fig. 20, it is clear that both the 20 and 30° die angles produced hydrostatic tension along the strip centerline over the range of reductions while the 10° die angle produced hydrostatic pressure at reductions of 20% or more per pass. In this example, light reductions and higher die angles are shown to promote central bursts due to the resulting hydrostatic tension along the centerline.

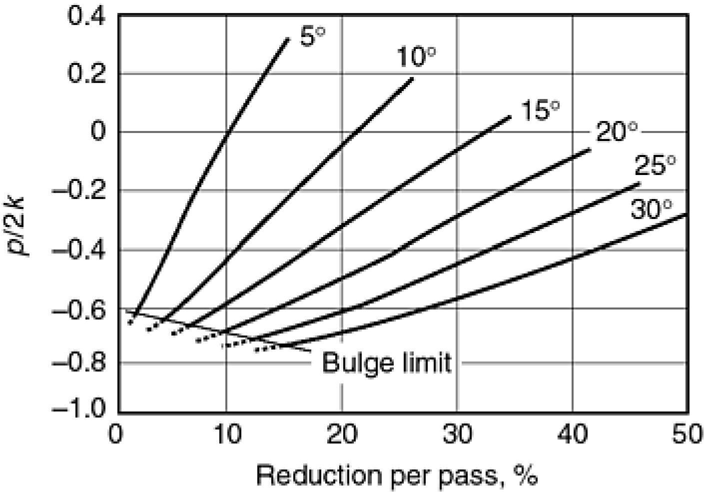

Fig. 20 **Ratio of hydrostatic pressure (*p*) to the tensile yield stress (2*k*) at the centerline of cold-drawn strip. The angles are semi-die angles; a positive *p*/2*k* value indicates pressure. Source: Ref 20**

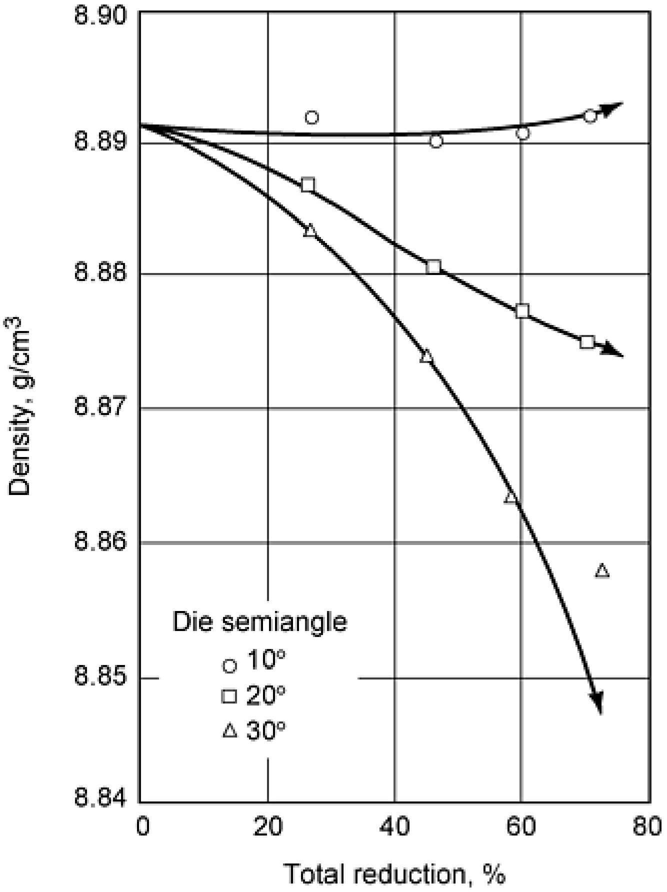

Fig. 21 Damage produced in the cold-drawn tough-pitch-copper strip as measured by density change with drawing reduction. Source: Ref 20

The conservative design approach is to ensure that no hydrostatic tension develops; this ensures that bursting will not occur. Often, however, the part or tooling design cannot be changed sufficiently to eliminate hydrostatic tension. If the level of hydrostatic tension can be kept below a critical level, bursting can likely be avoided. This may be accomplished by a change in lubricant, die profile, temperature, deformation level, or process rate.

Formability

Formability is a term that is similar to workability, only it is generally associated with sheet metal behavior. Forming sheet metal involves locally deforming a region or regions of the sheet, and the stress state that develops in the sheet and the strain path that various locations experience dictate whether or not the process is successful. Keeler and Goodwin

developed the concept of a forming limit diagram (FLD); it divides major-minor surface strain space into safe and failure regions. An FLD for aluminum-killed steel sheet is shown in Fig. 22, with failure indicating that either a neck or a tear has occurred. Several features of the FLD are important. First, the lowest point on the curve is at the plane strain position where the minor strain is 0. Second, while a sharp line is drawn, the FLD position is statistical in nature, just as with the workability limit discussed above. Third, the limit moves up as the sheet thickness is increased. In addition to thickness, the vertical position of the FLD and to some extent its shape are functions of chemistry, second-phase content, grain size and shape, and the presence of a crystallographic texture. The strain path followed during the forming operation is a function of friction, die and punch geometry, hold-down pressure, and the work-hardening behavior of the metal.

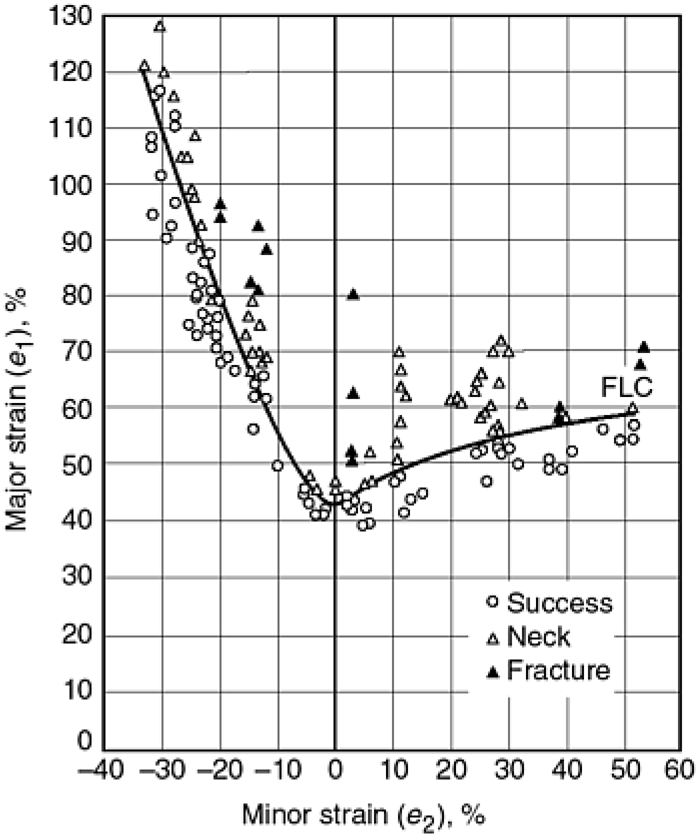

Fig. 22 Forming limit diagram for aluminum-killed steel sheet. Source: Ref 21

Two metallurgical parameters that are used to rank sheet forming characteristics are the work hardening exponent, *n*, and the resistance to thinning in the thickness direction, *r* (normal anisotropy). The average of *r* in the plane of the rolled sheet is $\bar{r}$. It seems reasonable that a metal with high work hardening has a high formability because work hardening prevents strain localization under tension and distributes deformation throughout the material. However, the contact area between the sheet and the punch may be so large that friction minimizes the natural ability of the metal to distribute strain. The result may be strain localization and tearing unless the sheet metal has a high resistance to strain in its through thickness direction. A high $\bar{r}$ indicates a high yield strength in the through thickness and good deep drawability as measured by the limiting draw ratio (LDR), that is, the ratio of the largest blank diameter to punch diameter that can be drawn through a die without tearing. Figure 23 shows typical LDR values versus $\bar{r}$ values for some common sheet metals. This normal anisotropic behavior is beneficial in this case.

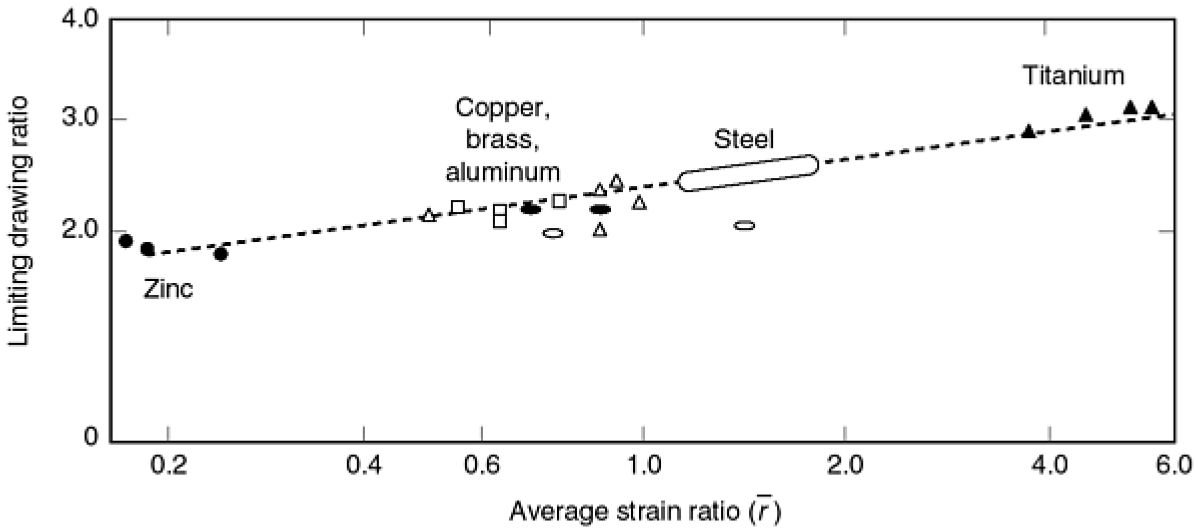

Fig. 23 Correlation between the limiting draw ratio (LDR) and $\bar{r}$ for selected sheet metals. Source: Ref 5

Rather than average *r* over a plane, another way to examine the effect of planar anisotropy is by Δr, which indicates the variation in *r* with direction in the plane of the sheet. For values of Δr less than or greater than 1, nonuniform straining during deep drawing will occur in directions parallel and normal to the rolling direction, resulting in the formation of ears. Ears are shown in Fig. 24(a), while 24(b) shows the orientation dependence on the ears with rolling direction for positive and negative Δr values. It is important for the process designer to know whether or not the sheet metal is subject to earing because an extra step is needed to trim away the ears.

Microstructural Effects on Metal Flow

Single-Phase versus Multiphase Microstructures. There is a considerable difference in mechanical behavior between pure metals and their alloys. A pure metal is by definition a single-phase, homogeneous material. An alloy may be a single phase that is strengthened by interstitial and/or substitutional methods. An alloy may also be a multiphase metal, with the alloy properties being a function of the properties of the individual phases. The actual alloy properties will be a function of the volume fraction of phases, the distribution of the phases, and the size/shape of the minor phase(s). Properties that are especially influenced include flow behavior, ductility, and toughness.

The four figures that are contained in Fig. 25 show schematically how workability is affected by temperature for single-phase and two-phase metals (Ref 13).

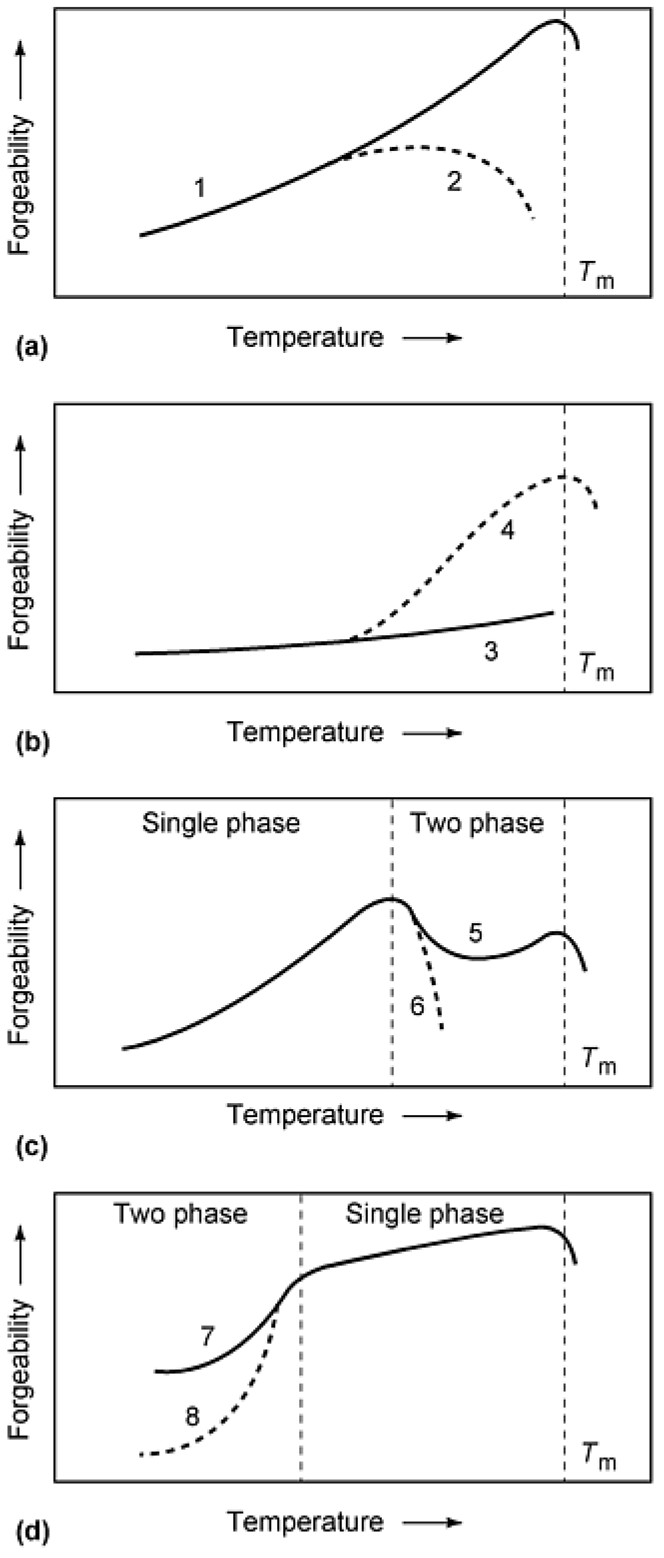

Fig. 25 Schematic curves depicting the forgeability of single-phase and two-phase alloys as a function of temperature. (a) Curve 1: pure metals and single-phase alloys (aluminum alloys, tantalum alloys, niobium alloys). Curve 2: pure metals and single-phase alloys exhibiting rapid grain growth (beryllium, magnesium alloys, tungsten alloys, all-β titanium alloys). (b) Curve 3: alloys containing elements that form insoluble compounds (resulfurized steel, stainless steel containing selenium). Curve 4: alloys containing elements that form soluble compounds (molybdenum alloys containing oxides, stainless steel containing soluble carbides or nitrides). (c) Curve 5: alloys forming ductile second phase on heating (high-chromium stainless steels). Curve 6: alloys forming low-melting second phase on heating (iron containing sulfur, magnesium alloys containing zinc). (d) Curve 7: alloys forming ductile second phase on cooling (carbon and low-alloy steels, α-β and α titanium alloys). Curve 8: alloys forming brittle second phase on cooling (superalloys, precipitation-hardenable

stainless steels). T_m, melting temperature, Source: Ref 13.

In Fig. 25(a), the workability for pure metals and single-phase alloys of aluminum, tantalum, and niobium are represented by curve 1. As temperature increases, workability increases for these metals. Curve 2 represents a single-phase metal that experiences rapid grain growth at elevated temperatures. For metals such as beryllium, magnesium, tungsten, and β-titanium alloys, workability increases with temperature until grain growth becomes excessive, and then it decreases.

Figure 25(b) contains two schematic curves for a single-phase metal matrix that contains a dispersion of second-phase particles. Curve 3 is representative for metals that contain insoluble particles; examples are iron with MnS inclusions and Se additions in stainless steel. Here, workability is generally low due to the deleterious effect of the second-phase compound on ductility and workability, and temperature has only a minor effect. If the second-phase compound is soluble at higher temperatures, a behavior like curve 4 results. At low temperatures, workability is poor due to the presence of the second phase, and once it has dissolved at higher temperatures, the workability is improved; examples include molybdenum oxides in molybdenum metal and stainless steel strengthened by vanadium carbides and nitrides.

Figure 25(c) contains schematic curves for a metal that is single phase at lower temperatures and two phases at higher temperatures. Curve 5 represents a metal that forms a ductile second phase. Curve 6 represents a curve for a metal that forms either a brittle second phase or a second phase that melts and causes hot shortness; sulfur in iron is an example where FeS may form and melt. Leaded steels can have a similar problem, although lead is always present as a second phase.

Figure 25(d) contains two curves for metals that are two phases at lower temperatures and a single phase at higher temperatures. The second phase at low temperature will be formed upon cooling from the high temperature, single-phase state. For curve 7, the second phase has some ductility, so a measure of workability is retained after it has formed. Low-carbon steels and low-alloy steels with low-carbon content are examples as these steels can be cold forged successfully. For curve 8, a brittle second phase is formed and cold workability is nil. Superalloys, which precipitation-harden, tend to behave in this manner, as do precipitation hardened stainless steels (the PH series).

While the curves in Fig. 25 are only of descriptive use, it is clear that the microstructural nature of the workpiece is important to its workability. Temperature and strain rate conditions must be accurately selected and controlled for acceptable forging.

As the curves in Fig. 25 indicate, the presence of a second phase is usually detrimental to ductility. Figure 26 shows schematically that as the percentage of alloying additions that contribute to the formation of a second phase increases, the acceptable forging window decreases. On the high-temperature side, workability is reduced by the increasing likelihood of low-melting phases. On the low-temperature side, a higher temperature is required due to the increasing volume fraction of second-phase particles. Figure 27 conveys a similar message for a variety of metals. As the inherent strength is increased (left to right), a higher forging load is required. As alloy additions are made that result in increasing amounts of second phases (top to bottom), the workability is decreased.

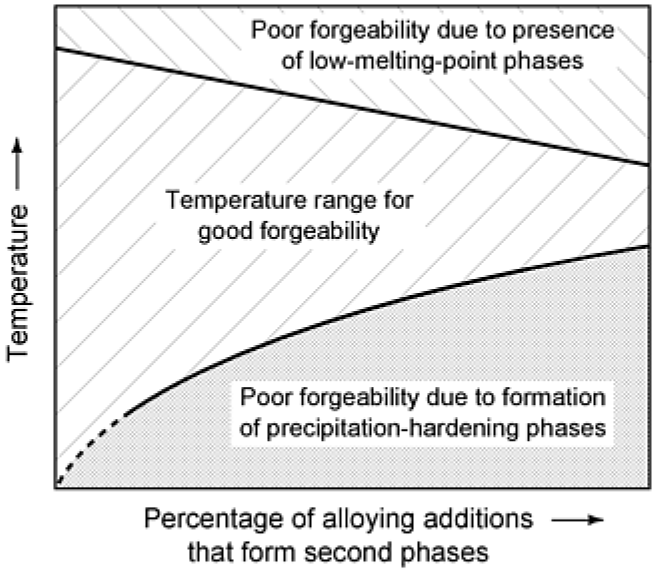

Fig. 26 Schematic effect of second phases on the working temperature range of alloys. Source: Ref 5

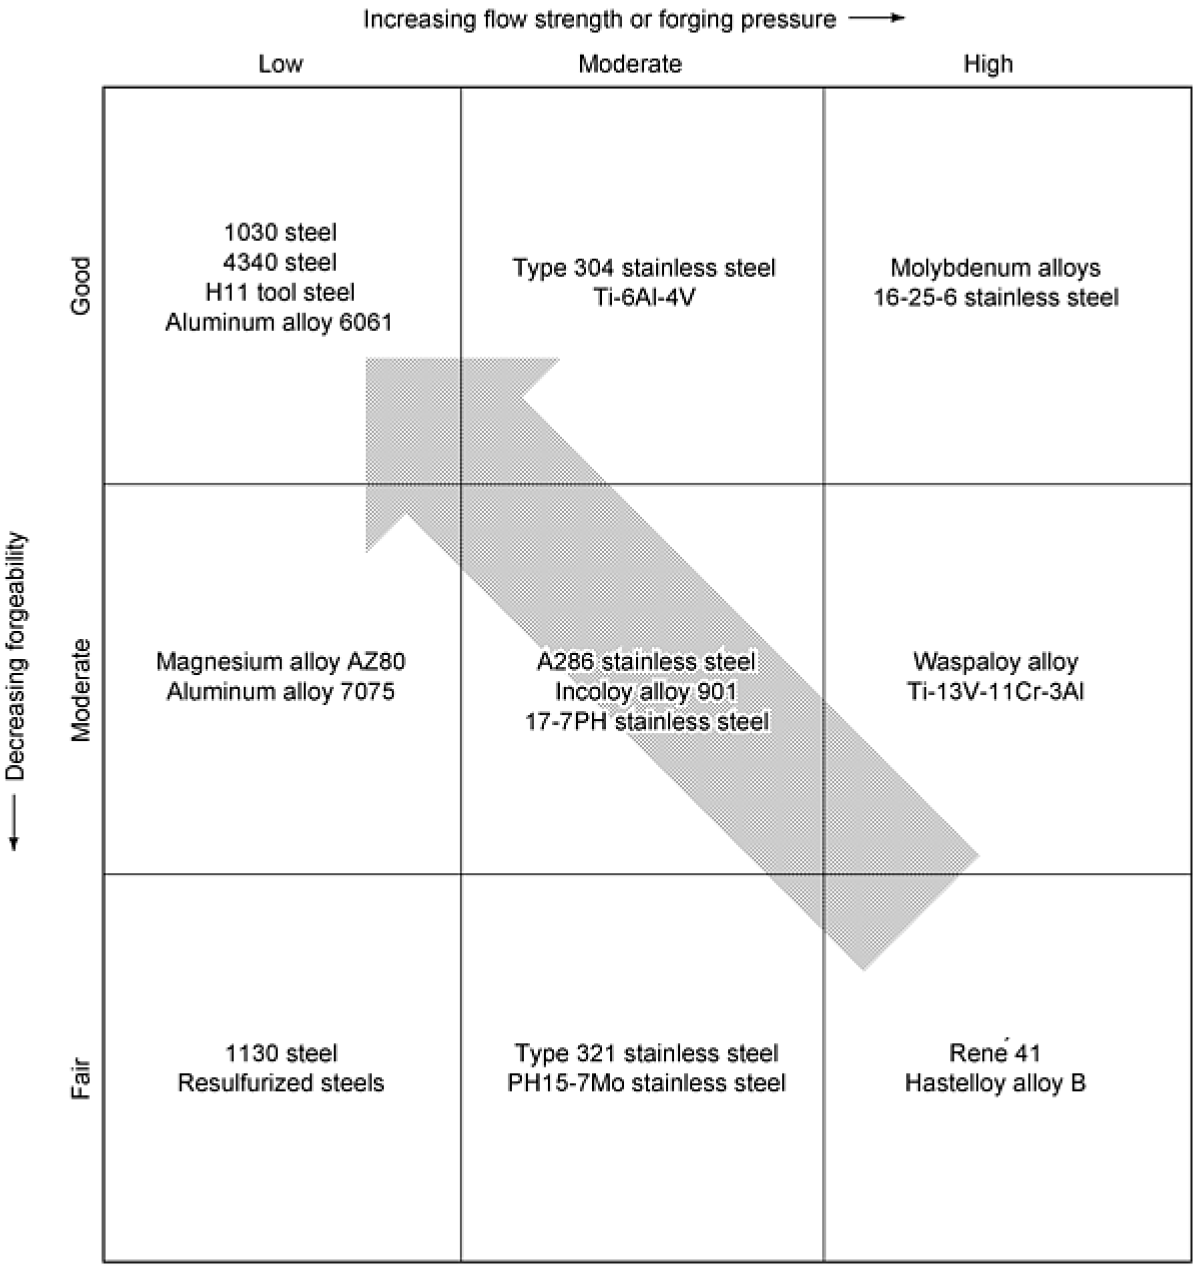

Fig. 27 Forging chart showing material effects on flow stress and workability. Arrow inside graph indicates increasing ease of die filling. Source: Ref 13

Hot Shortness and Burning. Time at temperature allows second phases to either dissolve or grow. If they dissolve, their effect disappears and workability improves. However, many of the second phases grow instead, and this can lead to decreased workability. In severe cases, local chemistry changes can interact with second phases to result in low-melting phases. These low-melting phases promote hot shortness. For example, Fig. 28 shows the severity of surface cracking in a copper bearing steel that has been oxidized. Alloying elements such as copper in the case of Fig. 28 or nickel and tin become enriched on the surface as other elements are preferentially oxidized. Copper has a limited solubility in austenite, and when its solubility limit is exceeded, a copper-rich phase is precipitated at austenite grain boundaries. This phase has a melting point lower than typical preheating temperatures for hot forging, and the liquid penetrates along grain boundaries and weakens them. During forging, the grain boundaries open and surface cracking occurs.

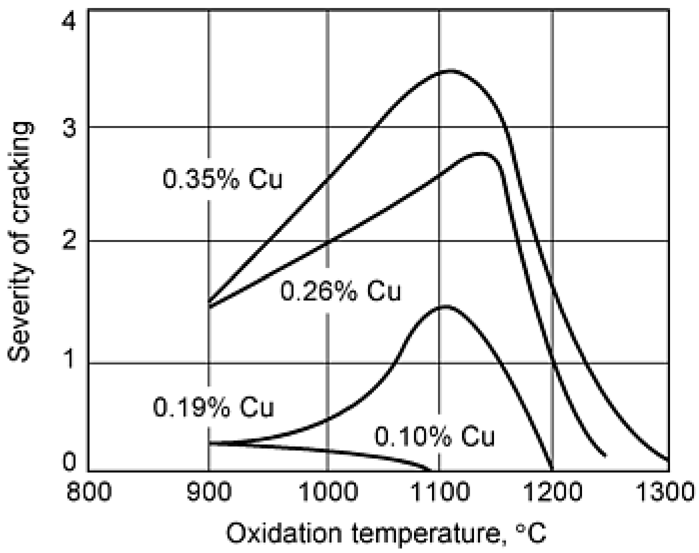

Fig. 28 Hot bend test results for low-carbon steels that have been oxidized prior to bending. Source: Ref 23

Burning is excessive overheating that results in very large austenite grains and excessive surface enrichment due to oxidation. As mentioned above, the surface enrichment can lead to the precipitation of low-melting phases. These cause local melting along grain boundaries. This effect cannot be removed except by physically removing the surface layer to the depth that burning was experienced. It is best to scrap burned workpieces rather than attempt to salvage them.

The process designer and the process engineer should anticipate the effects of environment on workpiece performance, especially high-temperature environments as in these cases. The interaction between the workpiece and the heating equipment is critical to the success of the deformation process because unanticipated reactions or conditions can lead to defects.

Grain Flow Pattern

Grain flow pattern refers to the combination of grain shape and stringering of nonmetallic inclusions that develop with metal flow. Together, these can produce a "fiber" in the workpiece that results in anisotropic behavior in the workpiece. The anisotropy is most easily identified by differences in ductility, toughness, and fatigue resistance for longitudinal, transverse, and short-transverse directions. Both hot and cold deformation result in directionality of mechanical properties in the forging, respectively.

Grain flow can be used effectively to produce a better forging. If the grain flow can be aligned in the direction of maximum tension in the part during service, superior performance will be achieved. The resistance to crack initiation and propagation is highest in the direction normal to the grain flow because the grain boundaries and elongated inclusions act to blunt advancing cracks. If the tension is normal to the fiber direction, the fiber will enhance crack propagation, hence transverse and especially through-thickness directions have lower dynamic properties such as toughness and fatigue than the longitudinal direction. This is shown in Fig. 29 for a manganese steel where ductility is increased from the level of the initial casting by forging deformation, with the longitudinal direction increasing the most. Figure 30 shows grain-flow patterns for a channel section forged with different parting-line locations. Because the grain-flow pattern breaks out to the part surface at the parting line, any stress during service that is normal to the parting line will act perpendicular to the weakest planes. These planes are the easiest to fracture along, for example, the short-transverse equivalent position. Because a channel will usually be stressed in a direction normal to it (flexing the channel legs to open or close), the grain-flow pattern in Fig. 30(b) is least detrimental.

Flow-Related Defects in Bulk Forming

Underfill may not seem like a flow-related defect, but aside from simple insufficient starting mass, the reasons for underfill are flow related. These include improper fill sequence, insufficient forging pressure, insufficient preheat temperature, lubricant build up in die corners, poor or uneven lubrication, and excessive die chill. An improper fill sequence may result in excessive flash loss, or it may be the result of extraordinary pressure requirements to fill a particular section. Sometimes, venting may eliminate the problem; more often than not, a change in the incoming workpiece shape or a change in the deformation sequence is required.

Important points to keep in mind are that the forging load increases very rapidly as the sharpness of details is increased, that flash geometry directly influences the amount of back pressure experienced by the metal in the die cavity, and that die wear increases directly with die pressure.

A lap or fold results from an improper progression in fill sequence. Normally, a lap or fold is associated with flow around a die corner, as in the case of an upper rib or lower rib, or with a reversal in metal-flow direction. A general rule of thumb is to keep metal moving in the same direction. The die corner radius is a critical tool dimension, and it should be as generous as possible. In progressing through a forging sequence, the die corners should become tighter, so that the workpiece fillets are initially large and progressively become smaller as the forging steps are completed. Figure 31 shows schematically a lap forming as metal flows around a die corner. An actual forging lap is shown in Fig. 32.

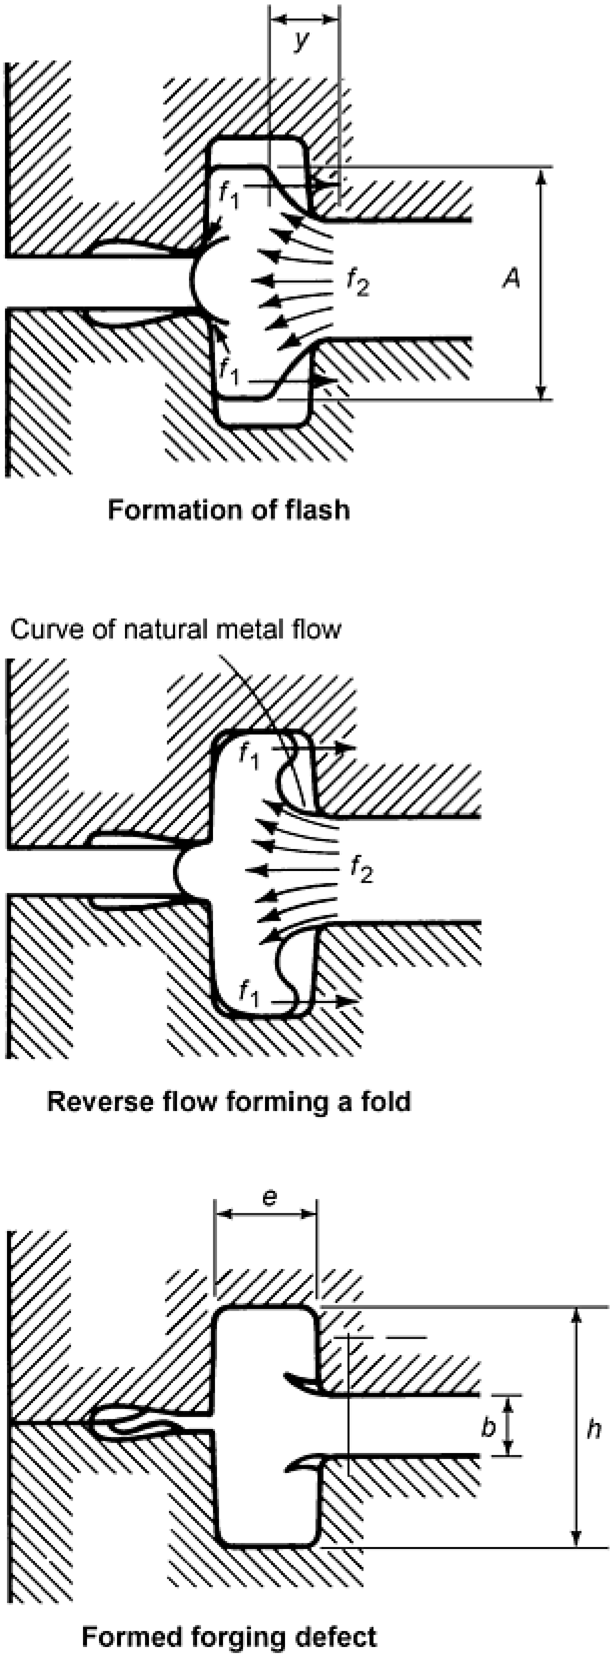

Fig. 31 Lap formation in a rib-web forging caused by improper radius in the preform die. Source: Ref 25

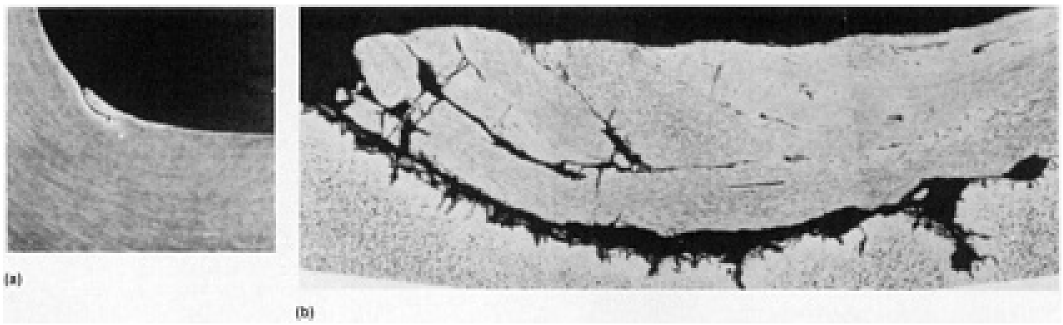

Fig. 32 Lap in a Ti-6Al-4V bulkhead forging. (a) 3.5×. (b) 50×. Source: Ref 26

Extrusion Defect, Pipe, or Suck-in. The tail of an extrusion is unusable because of nonuniform flow through the extrusion die. This results in a center-to-surface-velocity gradient, with metal from the workpiece interior moving through the die at a slightly higher velocity than the outer material. The result shows up at the tail of the extrusion as a suck-in or pipe, and, for extrusions, the tail is simply cut off and discarded. Alternatively, a follower block of cheaper material may be added so that most of the defect falls in the cheaper material, and less length of the extruded workpiece is lost.

For forgings that involve forward or backward extrusion to fill a part section, the same situation can develop. Metal flow into a rib or hub can result in a suck-in defect, which in a worst-case scenario would show up as a fold on the face opposite to the rib, and a best case would be a depression on what otherwise should be a flat surface. As shown schematically in Fig. 33, metal flowing up into the hub does not generate sufficient back pressure to maintain underside contact. One method of eliminating this type of defect is to position more material on the back face initially. Another method is to change the rib geometry (aspect ratio and/or angles). If neither of these changes can be accomplished, an extra forging step may be needed to limit the amount of extrusion that is done in any one step.

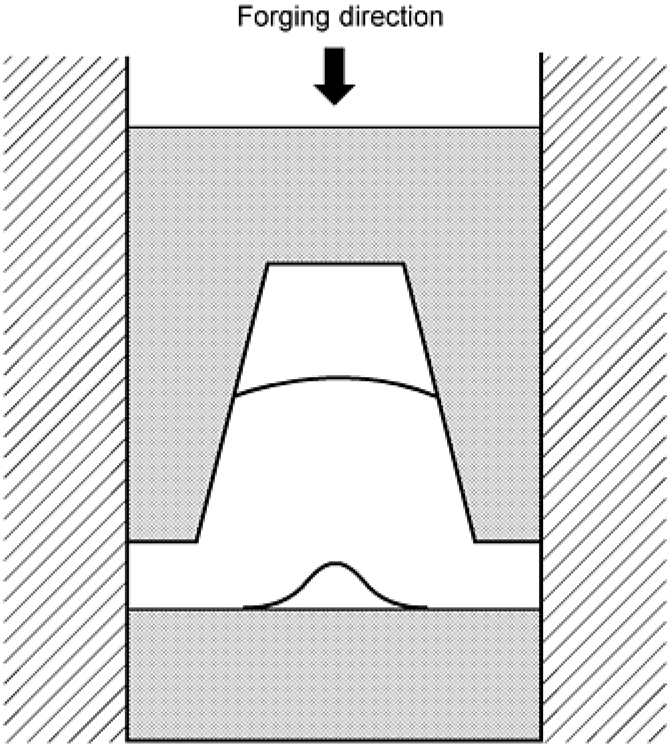

Fig. 33 Schematic showing the formation of a "suck-in" defect

Shear-Related or Flow-Through Defects. Shearing defects are also known as flow-through defects because they result from excessive metal flow past a filled detail of the part. An example of this is shown in Fig. 34 for a trapped-die forging that has a rib on the top surface. The rib denoted by "2" is filled early in the forging sequence, and significant mass must flow past the rib in order to fill the inner hub, zone "4." The result can be a complete shearing-off of the rib in the worst case, with a lesser case being the formation of a shear-type crack.

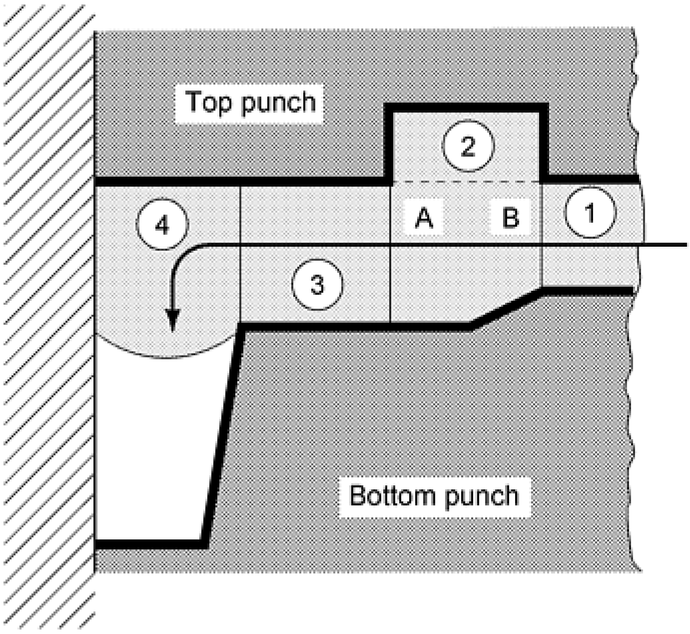

Fig. 34 Schematic of a flow through crack at the base of a rib in a trapped-die forging. Excessive metal flow past region 2 causes a shear crack to form at A and propagate toward B. Source: Ref 12

Design for Deformation Processes

B. Lynn Ferguson, Deformation Control Technology, Inc.

Defects in Sheet Metal Parts

Defects in sheet-metal formed parts are often appearance related rather than mechanical in nature. A primary example of a cosmetic defect is stretcher strains, or Lüder's bands, in steel parts. Mold steel displays discontinuous yield behavior as shown in Fig. 35. A sharp yield drop, followed by yield extension, known as Lüder's strain, at a lower level of stress,

followed by normal work hardening in a tension test is the indicator of this behavior. If the part-forming operation imposes a low level of strain, Lüder's strain is often visible; Fig. 36 shows Lüder's strain as concentrated bands of deformation. Painting will not hide these bands, so for a smooth, mirrorlike finish, they must be avoided.

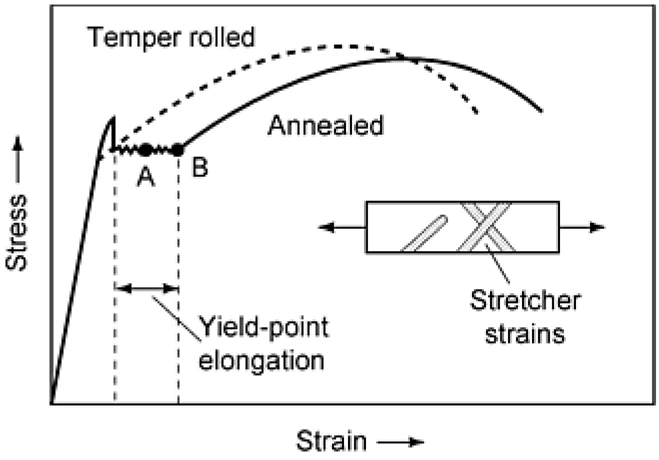

Fig. 35 Tensile stress-strain curve for a low-carbon steel showing yield drop and stretcher strains (Lüder's strains). Temper rolling removes the discontinuous yield behavior. Source: Ref 5

Fig. 36 Stretcher strains (Lüder's bands) in rimmed 1008 steel

A mechanism known as strain aging is responsible for the discontinuous yield behavior. It can be temporarily eliminated by temper rolling the sheet or by stretcher leveling it such that it is deformed into the work-hardening region of the stress-strain curve. As Fig. 35 depicts, temper-rolled sheet will not exhibit discontinuous yielding or Lüder's strains if it is formed within a certain time period, for example, a few days. However, if the sheet is stored for several weeks before it is processed into parts, strain aging will have occurred and the Lüder's strain will be present in the yield behavior of the sheet. Again, the process engineer and the process designer should be aware of this phenomenon so that it can be avoided, or at least anticipated.

Necks, both diffuse and localized, are another surface-related defect, and these indicate mechanical instability of the sheet. Necks are thinned regions of the sheet, so they result in a mechanically weakened zone. In the extreme case, a neck leads to cracking. The corner of flat-bottomed cans is a typical area that experiences problems of localized thinning and tearing. A material with a high *r* lessens this problem.

Another defect is called wrinkling, although it is actually a buckle. Wrinkles tend to be problems along the flanges of deep-drawn shapes. As a blank is drawn into a die cavity, sheet thickening occurs in the flange because the flow is converging in nature. If the hold-down pressure is not sufficient, the sheet in the flange area will wrinkle, as shown in Fig. 37. Using an initially equal hold-down pressure around the flange, the corners thicken more than the main lengths of the

flange, so the resultant hold-down becomes nonuniform. The main lengths of the flange do not adequately clamp the blank and it wrinkles. The sheet must experience a minimum hold-down pressure to avoid wrinkling. However, if the hold-down pressure is too high, it will cause tearing by restricting metal thickening that must occur as the blank edges are drawn toward the die. Figure 38 shows a balance between the wrinkling hold-down pressure limit and the excessive hold-down limit for drawing the aluminum pan shown in Fig. 37. The initial blank shape affects the volume of metal being drawn toward the die cavity and, thus the pressure needed to counter wrinkling. As shown, a rectangular blank requires a higher hold-down pressure than an oblong or oval blank because it has slightly greater metal volume, especially in the corners where the metal flow is more axisymmetric in nature.

Conclusions

Deformation processing has its origins in ancient manufacturing techniques, and although these processes may be referred to as "low-tech" or "rust-belt" technology, this field is complex. These processes have the capability of producing a precision part or product form with a specified microstructure at high rates of production *if* the process is properly matched with the workpiece material and it is well controlled. There are many process variables, both mechanical and metallurgical in nature, and it is the interaction of the process conditions of rate, temperature, and shape with the metallurgical conditions of flow stress, workability, and microstructure that dictate the success or failure of the process. Both the process designer and the product designer have many analytical tools available, and these tools (as discussed in the article "Modeling of Manufacturing Processes" in this Volume) should be used to assist in making critical geometry, material, and deformation process decisions.

Design for Powder Metallurgy

Howard I. Sanderow, Management & Engineering Technologies

Introduction

THE POWDER METALLURGY (P/M) process is a near-net or net-shape manufacturing process that combines the features of shape-making technology for powder compaction with the development of final material and design properties (physical and mechanical) during subsequent densification or consolidation processes (e.g., sintering). It is critical to recognize this interrelationship at the outset of the design process because a subtle change in the manufacturing process can cause a significant change in material properties.

Note: Portions of the article have been adapted from *Powder Metallurgy Design Manual*, 2nd ed., Metal Powder Industries Federation, 1995. Used with permission.

Design for Powder Metallurgy

Howard I. Sanderow, Management & Engineering Technologies

General P/M Design Considerations

To begin a design using powder processing, six key design considerations must be recognized. With the variety of powder processing schemes available, the selection of the appropriate method depends to a great extent on these design constraints.

Size. Due to the physical nature of the processes and the physical limits of commercial manufacturing equipment, product size has certain critical boundaries. For some powder processes, the product size is quite limited (such as metal injection molding, MIM), while for hot-isostatic pressing (HIP) size is not considered a serious constraint.

Shape Complexity. Powder metallurgy is a flexible process capable of producing complex shapes. The ability to develop complex shapes in powder processing is determined by the method used to consolidate the powders. Because a die or mold provides the container for the consolidation step, the ease of manufacture of the container and the ability to remove a green compact (unsintered) from the container, in most cases, determines the allowable shape complexity of a given part.

Tolerances. Control of dimensional tolerances, a demanding feature of all near-net or net-shape manufacturing processes, is a complex issue in powder processing. Tolerances are determined by such process parameters as powder characteristics, compaction parameters, and the sinter cycle. The amount of densification during sintering and the uniformity of that shrinkage controls dimensional tolerance in most P/M products. Due to the very small amount of size change during sintering conventional press-and-sinter P/M parts, these products typically have the closest dimensional tolerances, as compared to HIP parts, which require the largest spread in tolerances.

Material Systems. Powder shape, size, and purity are important factors in the application of a powder processing technique. For some consolidation processes or steps, powders must be smooth, spherical particles, but for other processes a much more irregular powder shape is required. Nearly every material and alloy system are available in powder form. For some materials such as cemented carbides, copper-tungsten composites and the refractory metals (tungsten, molybdenum, tantalum, etc.) powder processing is the only commercially viable manufacturing process.

As an example, for "press and sinter" processing an irregular powder shape and distribution of particle sizes are desired for adequate green strength and sinter response. Hot isostatic pressing requires spherical powders (gas atomized) for lowest impurities and good particle packing. The MIM process also prefers spherical particles, but very small particle size (10-20 μm) is needed to ensure proper rheology, homogeneous distribution in the plastic binder, and excellent sinter response.

Properties. The functional response of any product is determined by its physical or mechanical properties. In powder processing these properties are influenced directly by the product density, the raw material (powder), and the processing conditions (most often the sintering cycle). As P/M materials deviate from full density, the properties decrease (as shown for the tensile properties--and electrical conductivity--of pure copper in Fig. 1). The mechanical response for 4% Ni steels is found in Fig. 2.

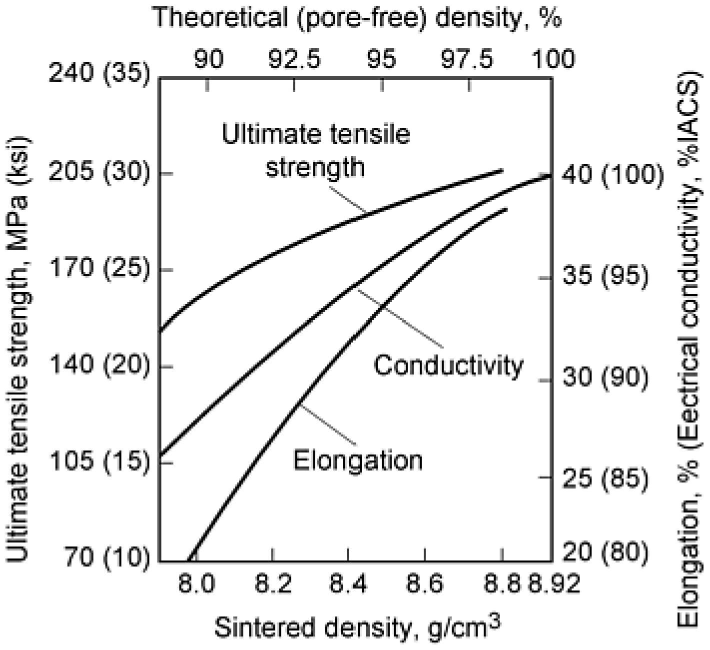

Fig. 1 Properties of pure copper. Source: Ref 1

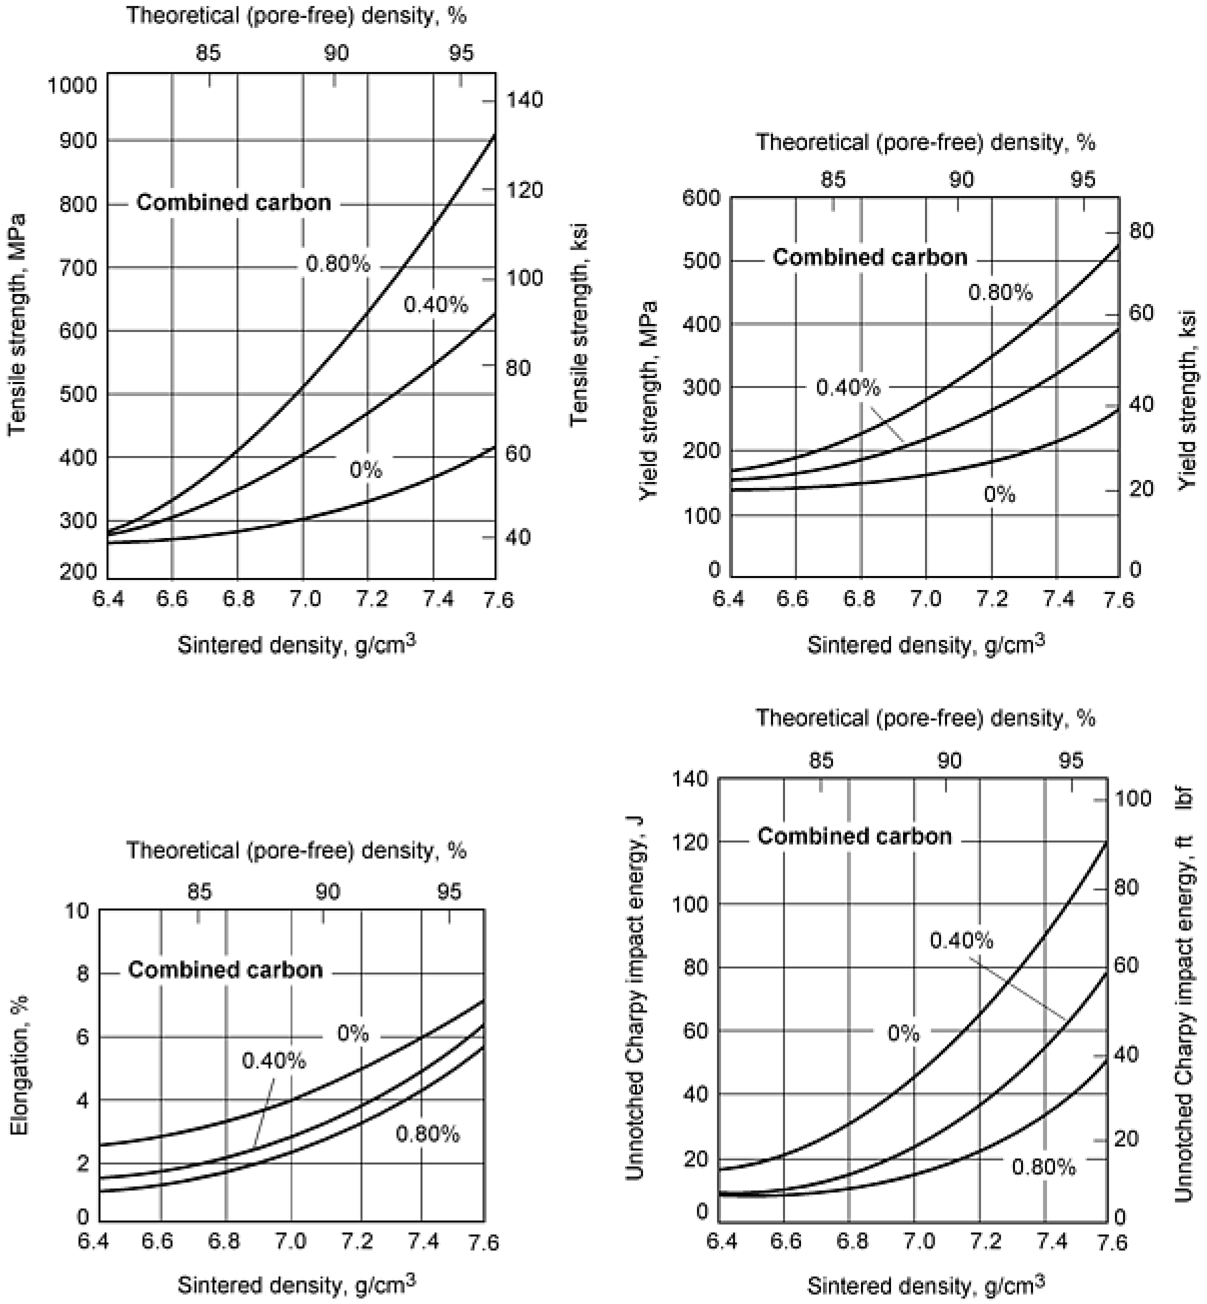

Fig. 2 Effects of density on mechanical properties of as-sintered 4% Ni steel. Source: Ref 2

Quantity and Cost. The economic feasibility of P/M processing is typically a function of the number of pieces being produced. For conventional press-and-sinter processing, production quantities of at least 1,000 to 10,000 pieces are desired in order to amortize the tooling investment. In contrast, isostatic processing can be feasible for much lower quantities, in some cases as small as 1 to 10 pieces. On a per pound basis, the approximate costs for steel P/M parts produced by various methods are roughly as follows:

Condition	Density range, g/cm^3	1997 selling price[(a)], $/lb
Pressed and sintered	6.0-7.1	2.45-2.70
Pressed, sintered, sized	6.0-7.1	2.90-3.20
Copper infiltrated	7.3-7.5	3.50-3.55
Warm formed	7.2-7.4	3.10-3.30
Double pressed and sintered	7.2-7.4	4.00-4.10
Metal injection molded	7.5-7.6	45.0-70.0
Hot forged	7.8	5.00-5.50
Double press and sinter + HIP	7.87	6.00-7.00

(a) These numbers are only averages; smaller parts are more expensive and larger parts less expensive per pound.

Design for Powder Metallurgy

Howard I. Sanderow, Management & Engineering Technologies

Powder Processing Techniques

In order to understand the design restrictions of each powder processing method, it is best to review these processes individually. The P/M manufacturing methods can be divided into two main categories: (1) conventional press-and-sinter methods and (2) full-density processes.

Conventional (Press-and-Sinter) Processes. The conventional press-and-sinter process technologies follow the steps outlined in Fig. 3. The various powder ingredients are selected to satisfy the process constraints and still meet the requirements of the end product. For example, in cold compaction irregularly shaped powders are used to ensure adequate green strength and structural integrity of the as-pressed product. Special solid lubricants are added to the powder blend to reduce friction between the powder particles and the tooling. If these lubricants might contaminate the metal powder particles, then an alternate consolidation method would be needed.

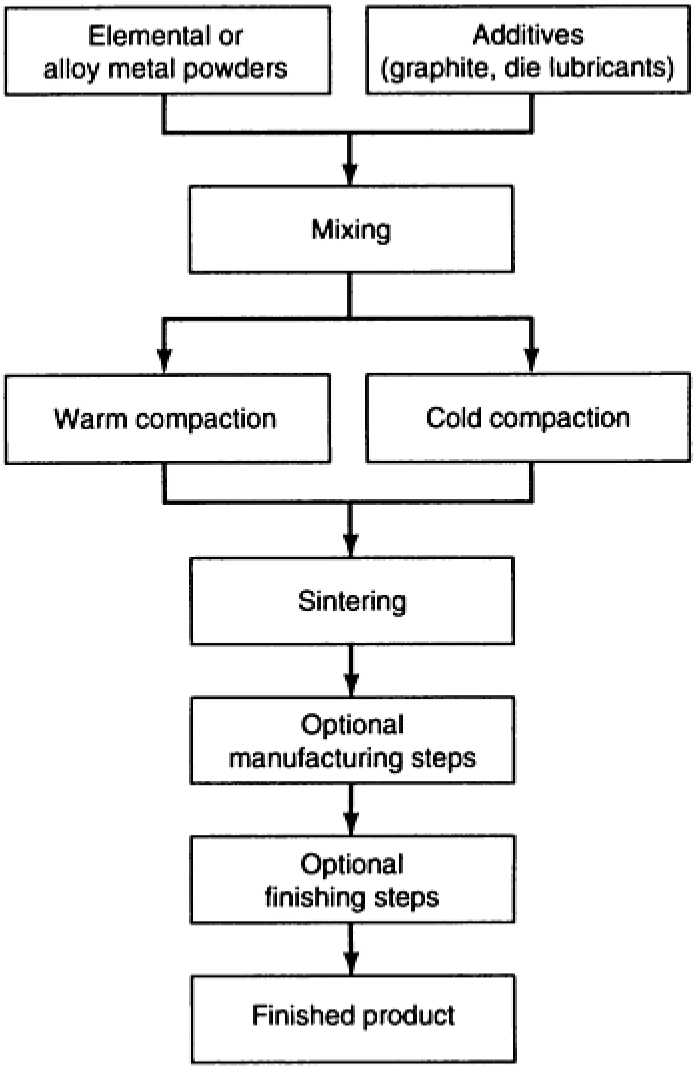

Fig. 3 General steps in the P/M process

Because powder is compacted in hard tooling using a vertical compaction motion, the product size and shape are limited by the constraints of available press capacity, powder compressibility, and the density level required in the product. For most conventional P/M products these limitations have a maximum size of about 160 cm^2 (25 $in.^2$) compaction area, part thickness of about 75 mm (3 in.), and a weight of 2.2 kg (5 lb). However, parts as large as 200 mm (8 in.) diameter by 100 mm (4 in.) thick, weighing 14.5 kg (32 lb) have been produced on conventional equipment. Even parts 380 mm (15 in.) in diameter by 6 mm ($\frac{1}{4}$ in.) thick have been produced by conventional P/M methods.

After compaction the green compact is sintered in a controlled-atmosphere furnace. Dimensional tolerance control is determined by the maximum temperature of the sintering cycle and the metallurgical changes that occur during sintering. If solid-state diffusion is the primary sintering mechanism, very little densification occurs, dimensional change is minimal and tolerance control is very good. This practice is followed for most P/M steels where size change during sintering is held to less than 0.3%. In contrast, other alloy systems utilize liquid-phase formation as the primary sintering mechanism, causing a significant increase in density, large dimensional changes, and much lower tolerance control. Examples of these material systems include cemented carbides where dimensional changes of 6 to 8% are typical and tolerance control is in the range of ±0.25 mm (±0.010 in.). In addition to its effects on dimensional tolerance levels, the sintering step also plays a significant role in determining the final physical and mechanical properties of the product. Higher sintering temperatures and longer sintering times promote pore rounding and increase densification, thereby improving critical mechanical properties such as tensile strength, ductility, impact resistance, and fatigue limit (see Table 1). The sintering process is extremely important in determining the magnetic response of soft magnetic P/M alloys. As shown in Table 2 for the Fe-0.45 wt% P alloy, increasing the hydrogen content in the sintering atmosphere and raising the sintering

temperature improved the maximum permeability more than 100%, the tensile strength more than 15%, and the ductility more than 300%. In a similar manner, the mechanical properties and corrosion resistance of P/M stainless steels are strongly dependent on the sintering process parameters (Ref 5).

(a) Balance N_2.

Warm compaction is used to increase the green density and green strength of P/M steel parts. When combined with high-temperature sintering, this process can provide mechanical properties equivalent to double press-double sinter processing at a lower cost. Due to the much higher green strength, warm compacted parts can be machined in the green condition. This technique can also be used to produce insulated magnetic cores, a composite material suitable for high-frequency electromagnetic systems.

Full-Density Processes. The second group of powder process technologies are formulated specifically to yield a product as close to full density as possible. This contrasts significantly with the previous conventionally processed products where attainment of full density was not the primary goal. The full-density processes include powder forging (P/F), metal injection molding (MIM), hot isostatic pressing (HIP), roll compaction, hot pressing, and extrusion.

Powder Forging. In P/F a preform is manufactured using conventional P/M process techniques and then hot formed in confined dies to cause sufficient material deformation that nearly all the porosity is eliminated. Due to the high costs in developing the preform design and maintaining forging tools and automated production systems of the P/F process, it has been limited, in most commercial practices, to high-volume products such as automotive connecting rods and transmission components. The P/F process has been successful in developing mechanical properties in P/F steel comparable to wrought steels (see Table 3). This process successfully overcomes the mechanical property limitations imposed by the residual porosity in conventional P/M products.

Table 3 Properties of powder forged steels

Alloy	Hardness, HRC	Tensile strength		Yield strength		Elongation, %	Impact toughness	
		MPa	**ksi**	**MPa**	**ksi**		**J**	**ft · lbf**
10C60	23	793	115	690	100	11	2.7	2

	48	1585	230	1310	190	10	13.5	10

Metal Injection Molding. The MIM process combines the structural benefits of metallic materials with the shape complexity of plastic injection molding technology. A uniform mixture of powder and binders is prepared and injected into a mold (see Fig. 4). The MIM powders are typically spherical in shape and much finer in particle size than those used for conventional cold-die compaction (MIM powder, 10-20 μm; conventional die-compaction powders, 50-150 μm). The binders are formulated specially to provide the proper rheological properties during injection molding as well as ease of binder removal after the molding step. Once the part is ejected from the mold, the binder material is removed using either solvent extraction or thermal processes (or both). After the debinding step the part is then sintered to complete the process. Due to the large amount of binder in the MIM starting material (up to 40% by volume), the MIM part undergoes a large reduction in size (as much as 20% linear shrinkage) during sintering. Dimensional tolerances, therefore, are not as good as in conventional die compaction and a straightening or coining step is sometimes needed.

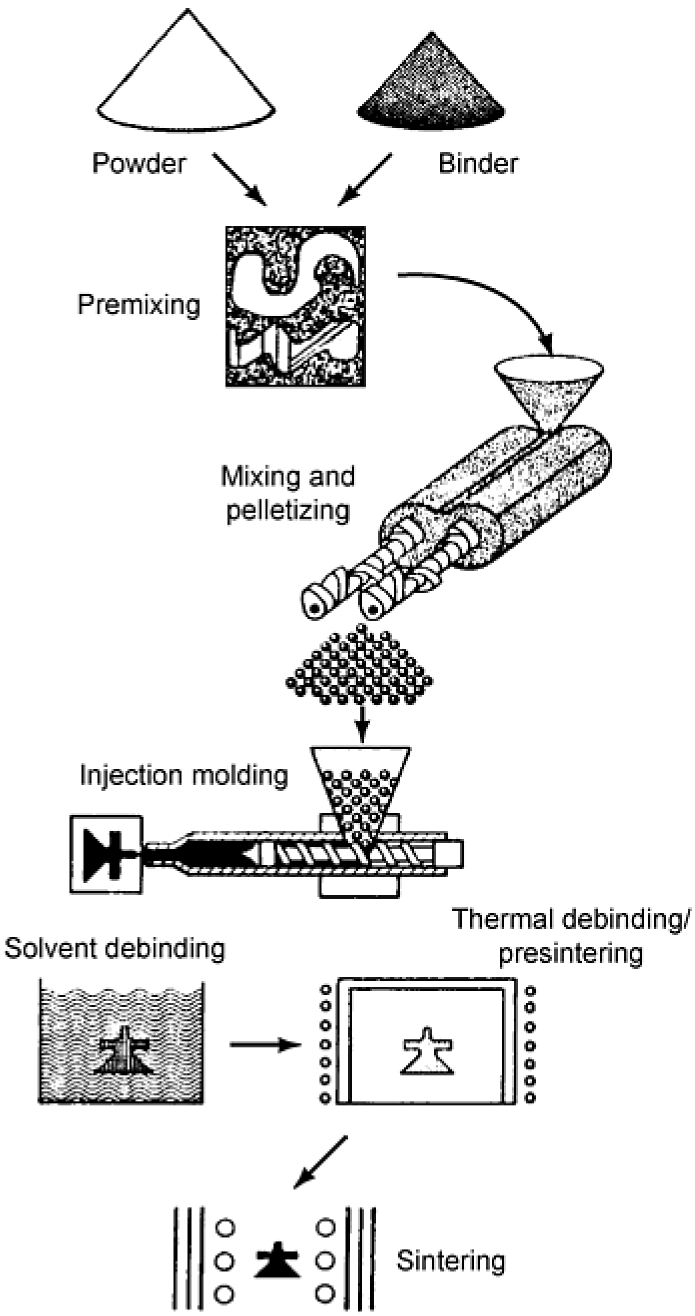

Fig. 4 Metal injection molding process. Source: Ref 7

Hot Isostatic Pressing. This fully dense process method is the least constrained technique. However, due to its very low production rate, costly equipment, and unique tool requirements, the HIP process is normally relegated to expensive materials such as tool steels, superalloys, titanium, and so forth. The process also requires high-purity powders (generally spherical in shape), and it is considered only a near-net-shape process. The powders are vibrated in place in a container, which is then evacuated and sealed. These metal or ceramic containers are placed in the HIP vessel, which applies an isostatic pressure (using a gaseous medium) and temperature to the container and the powder mass. This combination of heat and pressure on the container consolidates the powder to its final shape, as defined by the initial container configuration. The container must be removed from the HIP part after the process cycle, typically by machining or chemical etching.

Other Full-Density Methods. The remaining full-density consolidation methods are used infrequently in commercial practice and are limited to specialty materials. For example, roll compaction is used to form certain soft magnetic alloys, composite materials, and compositions unique to powder metallurgy. Hot pressing is used when the deformation

characteristics of the base powder require high temperatures to achieve plastic flow and adequate consolidation. The powder extrusion process requires a container, and it is similar to roll compaction and limited to specialty materials not suitable for conventional extrusion methods, such as composites, titanium, and nuclear materials.

Comparison of Powder Processing Methods

Effective application of powder processing methods requires a general comparison of the major design features, focusing on the similarities, differences, advantages, and disadvantages of each method. Table 4 provides a qualitative comparison, while Table 5 offers more specific design information. Characteristics for each processing method are summarized below.

Conventional die compaction:

- Widest range of most frequently used engineering materials, including iron, steel, stainless steel, brass, bronze, copper, and aluminum
- Most applicable to medium-to-high production volumes; small- to medium-size parts such as gears, sprockets, pulleys, cams, levers, and pressure plates (automotive, appliances, power tools, sporting equipment, office machines, and garden tractors are typical markets)
- Greatest density range, including high-porosity filters, self-lubricating bearings, and high-performance structural parts
- Limited physical and mechanical properties caused by residual porosity
- Most cost-competitive of the powder processes
- Wide range of applications from low- to high-stress applications

Powder forging:

- Potentially applicable to all engineering materials now hot forged, but actual applications currently limited to low-alloy steels
- Product applications limited to high-volume products such as automotive connecting rods and transmission components as well as power tool parts
- Mechanical properties equivalent to wrought steel
- Most cost-competitive of the full-density processes for medium-to-large parts

Metal injection molding:

- Limited range of materials, though most standard engineering alloys available as well as several specialty alloys
- Limited to relatively small, highly complex shaped products for medium-to-high production volumes
- Greatest range in shape complexity including high aspect ratios
- More costly than conventional die-compaction processes
- Superior physical and mechanical properties as compared to conventional process, due to higher density

Hot isostatic pressing:

- Materials limited only by the inherent cost of the process, therefore typically applied only to expensive materials
- Most suited for low-to-medium production volumes
- Competitive against large casting or forging products where substantial machining is needed to obtain the final product
- Much shape detail is machined after HIP processing; not normally a "net-shape" manufacturing process
- Physical and mechanical properties meet or exceed those of cast or wrought materials

Table 4 Comparison of powder processing methods

Characteristic	Conventional	MIM	HIP	P/F
Size	Good	Fair	Excellent	Good
Shape complexity	Good	Excellent	Very good	Good
Density	Fair	Very good	Excellent	Excellent
Dimensional tolerance	Excellent	Good	Poor	Very good
Production rate	Excellent	Good	Poor	Excellent
Cost	Excellent	Good	Poor	Very good

Table 5 Application of powder processing methods

	Conventional die compaction	MIM	HIP	P/F
Material	Steel, stainless steel, brass, copper	Steel, stainless steel	Superalloys, titanium, stainless steel, tool steel	Steel
Production quantity	>5000	>5000	1-1000	>10,000
Size, lb	<5	$< \frac{1}{4}$	5-5000	<5
Dimensional tolerance	±0.001 in./in.	±0.003 in./in.	±0.020 in./in.	±0.0015 in./in.
Mechanical properties	~80-90% wrought	~90-95% wrought	Greater than wrought	Equal to wrought
Price per pound	$0.50-5.00	$1-10	>$100	$1-5

Design for Powder Metallurgy

Howard I. Sanderow, Management & Engineering Technologies

Design Issues

The specific design issues for the powder process technologies would require an extensive discussion well beyond the limits of this article. An excellent source for additional details is the manual on P/M product design prepared by the Metal Powder Industries Federation (MPIF) trade association (Ref 8). Much of the sections that follow have been taken from that manual.

Conventional Die Compaction

In order to use die-compaction technology effectively, the designer must be familiar with the limitations and design constraints related to product shape and special features. The requirements for secondary operations focus on the effect of residual porosity on these process steps. Material selection and the design approach to be used conclude this discussion. Throughout this section structural parts are used to describe these design issues. Specific information on bearings and porous products is given in a separate section.

Shapes and Features. A shape or feature can be die compacted provided that (1) it can be ejected from the tooling and (2) the tools that form the feature have sufficient strength to withstand the repeated compaction loads. Due to the vertical closure of the tooling and the lack of tool motions perpendicular to the pressing direction, part removal from the tools controls many features. Examples of features that cannot be accommodated in die compaction, and therefore require secondary machining operations, include: undercuts, reverse taper (larger on bottom than on top), annular grooves and threads. The following guidelines provide assistance with many possible features in die compaction.

Wall Thickness. Minimum wall thickness is governed by overall part size and shape. For parts of any appreciable length, walls should be not less than 1.5 mm (0.060 in.) thick (Fig. 5). A maximum length-to-wall thickness ratio of 8 to 1 should be followed to ensure reasonable density uniformity and adequate tool life. Separate tool members (punches) should be used to provide density uniformity and proper ejection.

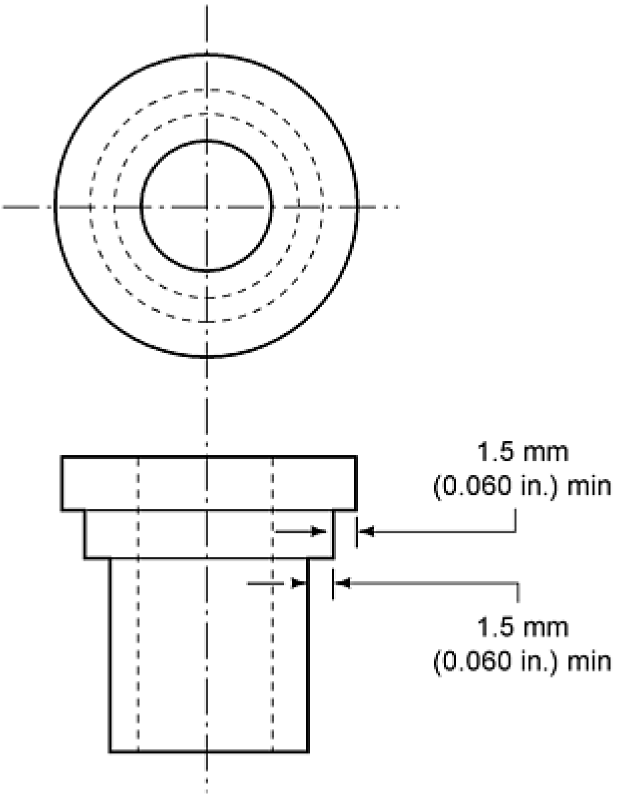

Fig. 5 Minimum wall thickness for conventional die compaction. Source: Ref 8

Steps. Simple steps or level changes not exceeding 15% of the overall part height (*H*) (Fig. 6) can be formed by face contours in the punches. A draft of 5° or more is needed to release this contour from the punch face during ejection. Features such as countersinks and counterbores can be similarly formed. This tooling method, as compared to multiple punches, will result in slight density variations from level to level. However, this approach offers the simplest tooling, lower-cost tooling, and closer axial tolerances than multiple punches.

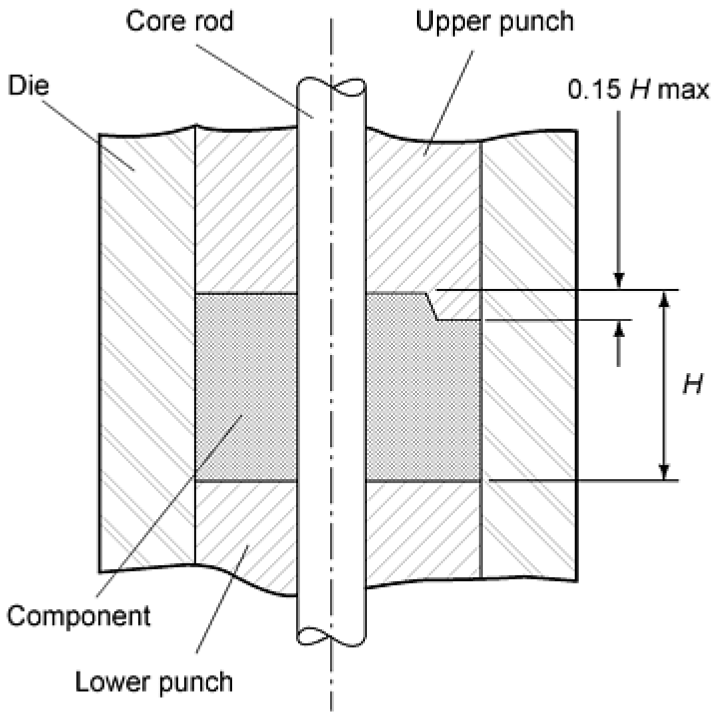

Fig. 6 Level change limit for P/M parts. Source: Ref 8

Spherical Shapes. Complete spheres cannot normally be made because the punches would have to feather to zero width (Fig. 7). Spherical parts require a flat area around a major diameter to allow the punch to terminate in a flat section (Fig. 7). Parts that must fit into ball sockets are repressed after sintering to remove the flats.

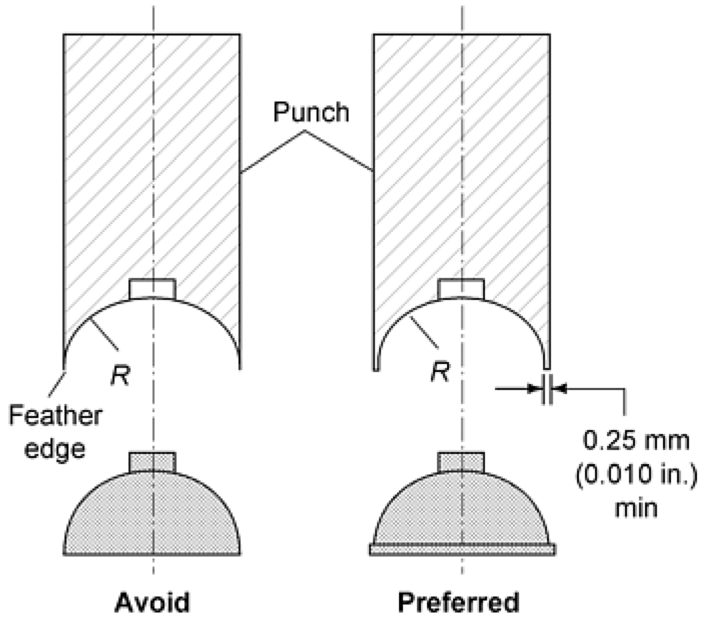

Fig. 7 Proper design of spherical shapes in P/M parts. Source: Ref 8

Taper and Draft. Draft is not generally required or desired on straight-through parts. While tapered side walls can be produced where required, the tools may demand a short straight surface (A in Fig. 8) at the end of the taper to prevent the punch from running into the taper in the die wall or on the core rod.

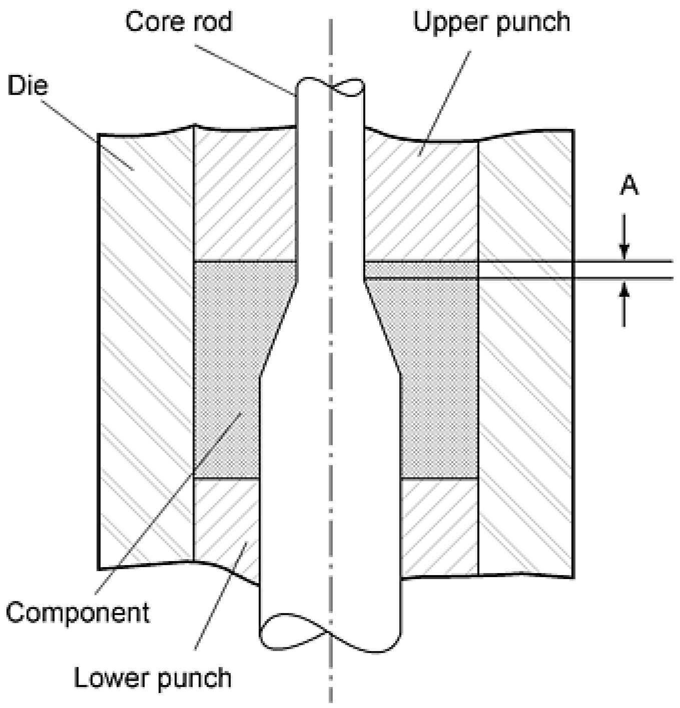

Fig. 8 Tapered hole design for P/M parts. Source: Ref 8

Holes. Through holes in the pressing direction are produced with core rods extending through the punches. Round holes require the least expensive tooling but many other shapes such as splines, keys, keyways, D-shapes, squares, and so forth can readily be produced. Blind holes, blind steps in holes, and tapered holes are also readily pressed. For very large parts, lightening holes are added to reduce weight and the area of compacted surface.

Flanges. A small flange, step, or overhang can be produced by a shelf or step in the die. Separate lower punches are used if the amount of overhang becomes too great to permit ejection without breaking the flange.

Alphanumeric Characters. Numbers, lettering, logos, and other characters can be pressed into surfaces oriented perpendicular to the pressing direction. Recessed lettering is preferred because raised letters are fragile, easily damaged in the green compact, and prevent stacking of parts for sintering.

Chamfers, Radii, and Bevels. Chamfers are preferred rather than radii on part edges to prevent burring. It is common practice to add a 0.25 mm (0.010 in.) flat at a 45° chamfer (Fig. 9); lower chamfer angles may not require the tooling flat.

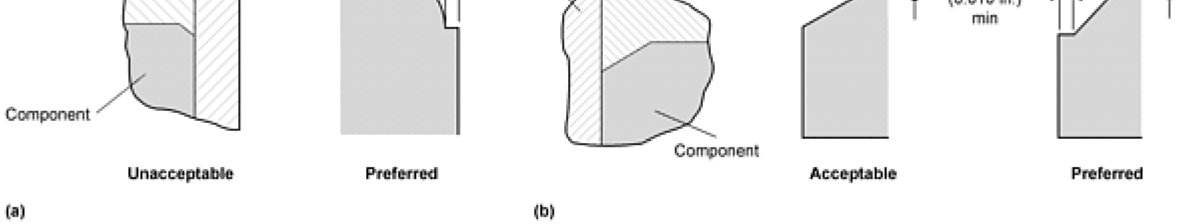

Fig. 9 Chamfer (a) and edge radii (b) design features. Source: Ref 8

Hubs and Bosses. Hubs or bosses that provide for drive or alignment rigidity in gears, sprockets, and cams can be readily produced. However, the design should ensure the maximum permissible material between the outside diameter of the hub and the root diameter of gear or sprocket features (Fig. 10).

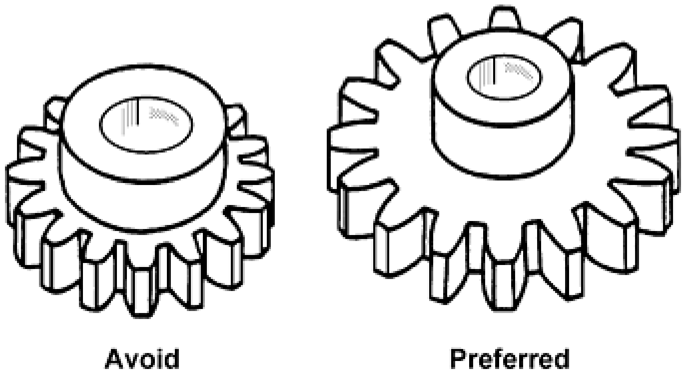

Fig. 10 Hub feature. Source: Ref 8

Other Features. Additional information on these and other features (slots, grooves, knurls, studs, fillets, countersinks, etc.) can be found in Ref 8. Examples of undesirable features that can cause tooling or powder compaction problems are shown in Fig. 11. Because shape complexity is a recognized limitation of die compaction, multipiece assembly is a useful alternative, especially where extensive machining would be required. Pulleys, spools, and sprockets have been produced using sinter bonding, brazing and welding techniques (Fig. 12).

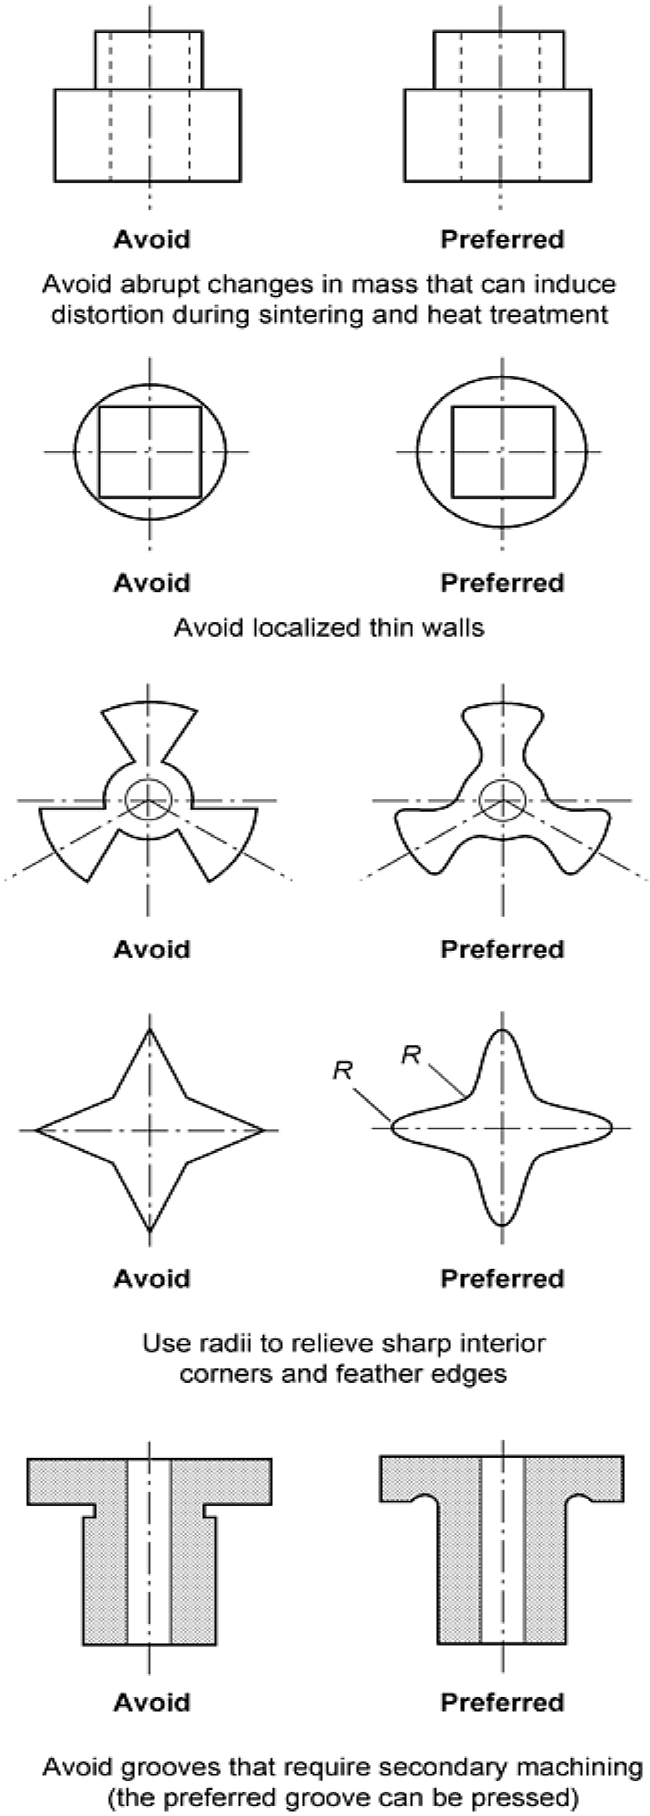

Fig. 11 Example of undesirable design features and preferred alternatives. Source: Ref 8

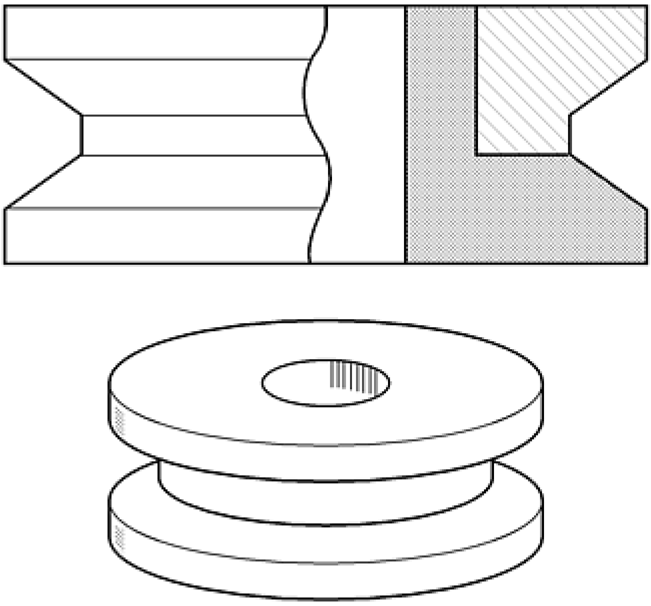

Fig. 12 Multipiece pulley design composed of bonded P/M parts. Source: Ref 8

Secondary Operations. A variety of secondary manufacturing and finishing operations may be required to complete the part, to improve properties, or to calibrate dimensional tolerances. Because die-compacted parts have residual porosity that may affect the response to these secondary operations, several guidelines are provided in this section.

Repressing. Die-compacted parts can be repressed in a second tool set in order to reduce the amount of porosity or reduce dimensional variation. By increasing the part density, critical physical and mechanical properties will be improved. This secondary densification step can be performed on the entire part or just specific features, for example, gear teeth. The sizing of P/M parts for improved dimensional tolerances is widely performed, especially for the manufacture of bearings.

Impregnation and Infiltration. Several procedures are used to fill the residual porosity in conventional P/M parts. Oil impregnation adds an internal lubricant to the product, which is useful in bearing and wear applications. The part can be resin impregnated to seal the pores for pressure tightness and improved machinability or to prevent the intrusion of undesired plating chemicals. Infiltration with a lower melting metal than the base material (such as copper-infiltrated steel or copper-infiltrated tungsten) is also used to seal porosity, but most often to increase mechanical properties or create unique composite structures.

Steam treating, also known as steam oxidizing, is a low-temperature (540 °C, or 1000 °F, 1 to 2 h) heat treatment process in which P/M steel parts are exposed to superheated steam. The process can be conducted in batch, pressurized furnaces or continuous belt furnaces. The steam reacts with the iron surface converting it to an adherent, protective blue-grey iron oxide (Fe_3O_4). Because the steam can penetrate the porosity, the oxide layer can be 0.020 to 0.050 in. deep depending on the processing conditions. Steam treating enhances the product by:

- Increasing wear resistance
- Increasing surface hardness
- Improving corrosion resistance
- Increasing compressive yield strength
- Providing low-pressure leak tightness

Formation of this oxide layer unfortunately reduces tensile strength and ductility, about 10 to 20%, depending on the material system and processing conditions.

Heat Treatment. Due to the presence of residual porosity in die-compacted P/M parts, heat-treat practices should utilize gaseous or noncorrosive liquid media (such as quench oil rather than water or fused salts). In addition, because the porosity allows for the penetration of gaseous media (i.e., carburizing gas), special steps must be considered when trying to develop a carburized case in P/M steels. The surface (or entire part) must be high enough in density to prevent the carburizing gas from penetrating the pore network. A density of 7.2 g/cm^3 or greater is desired. Copper infiltration can also be used to seal the part for a case-carburizing treatment. Heat treatment of P/M steels is most effective in improving mechanical properties when parts have a density greater than 7.0 g/cm^3.

Finishing. The variety of finishing operations--machining, plating, deburring, joining--must also consider the effects of residual porosity. Improvements in machinability have been achieved through resin impregnation (seals the porosity) and by adding machinability aids to the original powder blend. Surface finishing may also require resin impregnation if the part density is low enough to allow entrapment of plating or finishing chemicals. These liquids can cause internal corrosion of the P/M part if allowed to penetrate the open porosity network. For welding and brazing, precautions are necessary to ensure a sound joint (Ref 8).

Material Selection. Once the die-compaction processing method has been selected the designer must consider the product configuration and material requirements. Previous sections have discussed the design constraints regarding shape and configuration. The next step in the procedure (see Fig. 13) is comparing the critical part performance requirements with the available P/M materials. Reference 5 serves as a very useful source of material property data. In many cases, more than one material can satisfy the design performance requirements. Therefore, the various production methods must be considered because these affect the ultimate cost of the product.

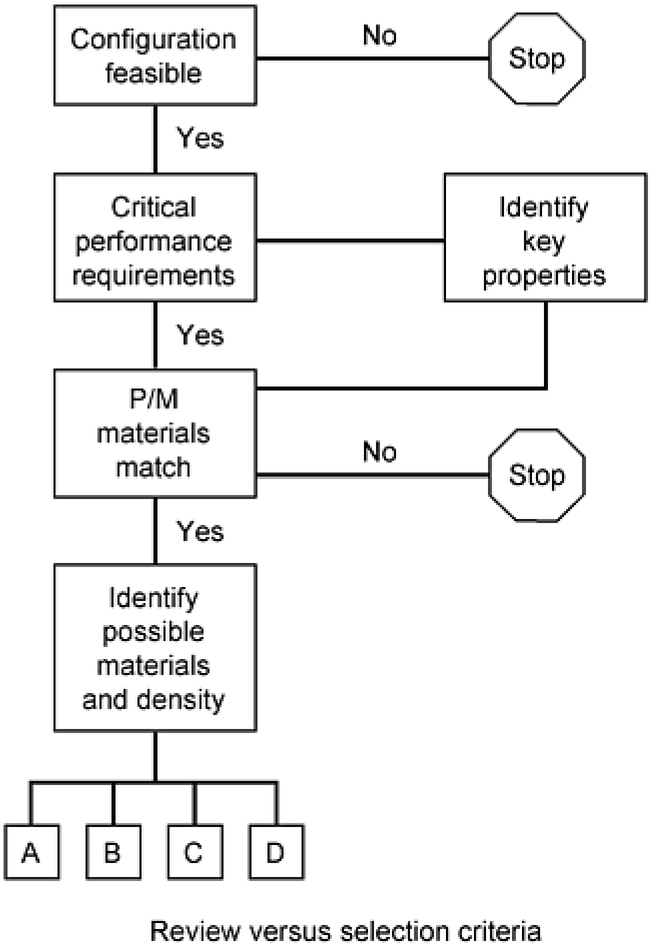

Fig. 13 Material selection method

Figure 14 provides the second evaluation scheme. Starting from the material selected, this leads directly to the density needed in the critical section of the part. Knowing the desired density leads to a preliminary selection of the powder and press size necessary to reach the required density. From this point the remainder of the processing steps are considered.

For example, is a conventional sintering process or a "high-temperature" process needed? Will a repressing-resintering process be necessary to achieve the density selected? What secondary processing treatments are needed, and how will the density affect these processes? Using a standard press-and-sinter process as a baseline, the cost of high-temperature sintering may add a 10 to 20% premium, while a double-press/double-sinter process could result in as much as a 40% premium. Therefore, the designer must recognize that selecting a material and density level leads directly to a processing cycle and the cost associated with the process. A judicious review and selection of materials can ensure the most cost-effective product design.

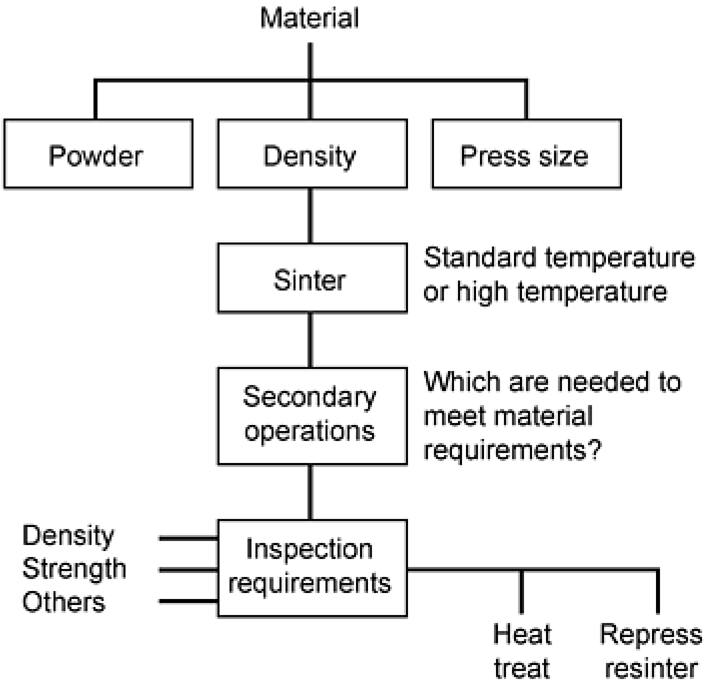

Fig. 14 How material selection affects process

Bearings

Due to the unique self-lubricating characteristics of P/M bearings, these products have additional design guidelines. After conventional die compaction and sintering, bearings are vacuum-oil impregnated to fill the interconnected porosity with oil. The design of P/M bearings and selection of the optimal alloy depend primarily on shaft velocity and bearing load. Other design factors include type of operation (stop-start versus continuous), shaft surface finish, type of lubricant, and conditions of uneven loading. The MPIF bearing standard (Ref 9) provides a systematic guide for these design issues:

- Recommended load as a function of shaft velocity
- Environmental factors that can reduce permissible loads
- Recommended press fits
- Running clearances
- Dimensional tolerances

The selection of a bearing alloy normally considers the following factors:

- Chemical compatibility with the lubricant
- Thermal conductivity to dissipate heat
- Mechanical properties to maintain structural integrity and withstand press-fit installation forces
- Antigalling with the shaft material
- Wear characteristics with the shaft material

Six commercial alloys dominate the self-lubricating bearing designs: bronze, diluted bronze, plain carbon steel, iron-copper alloys, copper steels, and iron-graphite. Graphite can be used as a solid lubricant and is added to the powder mix prior to compacting. More information on these materials can be found in Ref 9.

In some products the designer can incorporate bearing surfaces into the part, thereby eliminating the need for separately fabricated and installed bearings. The following design restrictions must be followed:

- Bearing areas should have a minimum of 10% interconnected porosity to provide sufficient oil capacity.
- Infiltration is not allowed in the bearing areas because the infiltration will fill the open pores.
- Machining on the bearing surfaces must be performed so as to avoid sealing or closing off the open porosity.

Metal Injection Molding

The MIM process is similar to plastic injection molding: (1) material is fed into the mold cavity through gates, which may leave a visible mark on the part; (2) the mold must open, leaving a parting line on the part; and (3) the part must be ejected from the mold cavity using ejector pins, which also may leave visible marks on the part. Location of the parting line is critical to the orientation of part features. To the extent possible, all features should be oriented perpendicular to the plane of the parting line to facilitate removing the part from the mold. Features not so oriented require additional tooling, such as side pulls.

The optimal location of gates is a design balance between product and processing requirements. In general, gates are located on the parting line, positioned to direct flow onto a core rod or cavity wall. Where wall thicknesses vary, gates are located so the material flows from thicker sections to thinner. Ejector pins push the molded part off of the mold cores. There must be enough pins to free the part off the core without damaging or distorting the as-molded part. Typically, these pins are located near features requiring the highest ejection forces, such as cored holes. Because the pins leave permanent marks, they should be positioned on recessed features, surfaces that will be machined, or unused areas such as runners.

Injection-molded parts are normally placed on flat plates or shelves for thermal debinding and sintering. A geometric feature that allows the part to rest securely with no additional support is preferred. Long spans, cantilevers, or delicate resting points may require special fixtures or setters to minimize distortion during sintering. A postsintering straightening operation may also be required.

Shape and Features. The design features that can be produced by MIM are similar to those made by conventional plastic injection molding or die casting. Dimensions and proportions are different due to the small size of MIM parts and molding characteristics of the MIM materials.

Draft. To facilitate release and ejection of the molded part, draft is normally in the range of $\frac{1}{2}$ to 2°. Draft should be uniform on all features of the part to facilitate mold fabrication and near the upper range with more complex part features or multiple cores.

Wall Thickness. Where feasible, walls should be of uniform thickness throughout the part (Fig. 15). Variations in thickness can lead to distortion, internal stresses, voids, cracking, and sink marks. In addition, thickness variations cause nonuniform shrinkage during sintering, leading to greater size variation and looser tolerances. A thickness in the range of 1.25 to 6.35 mm (0.050 to 0.250 in.) is preferred. Common ways of modifying a part to make wall thickness more uniform or ease the transition from thick to thin are shown in Fig. 16.

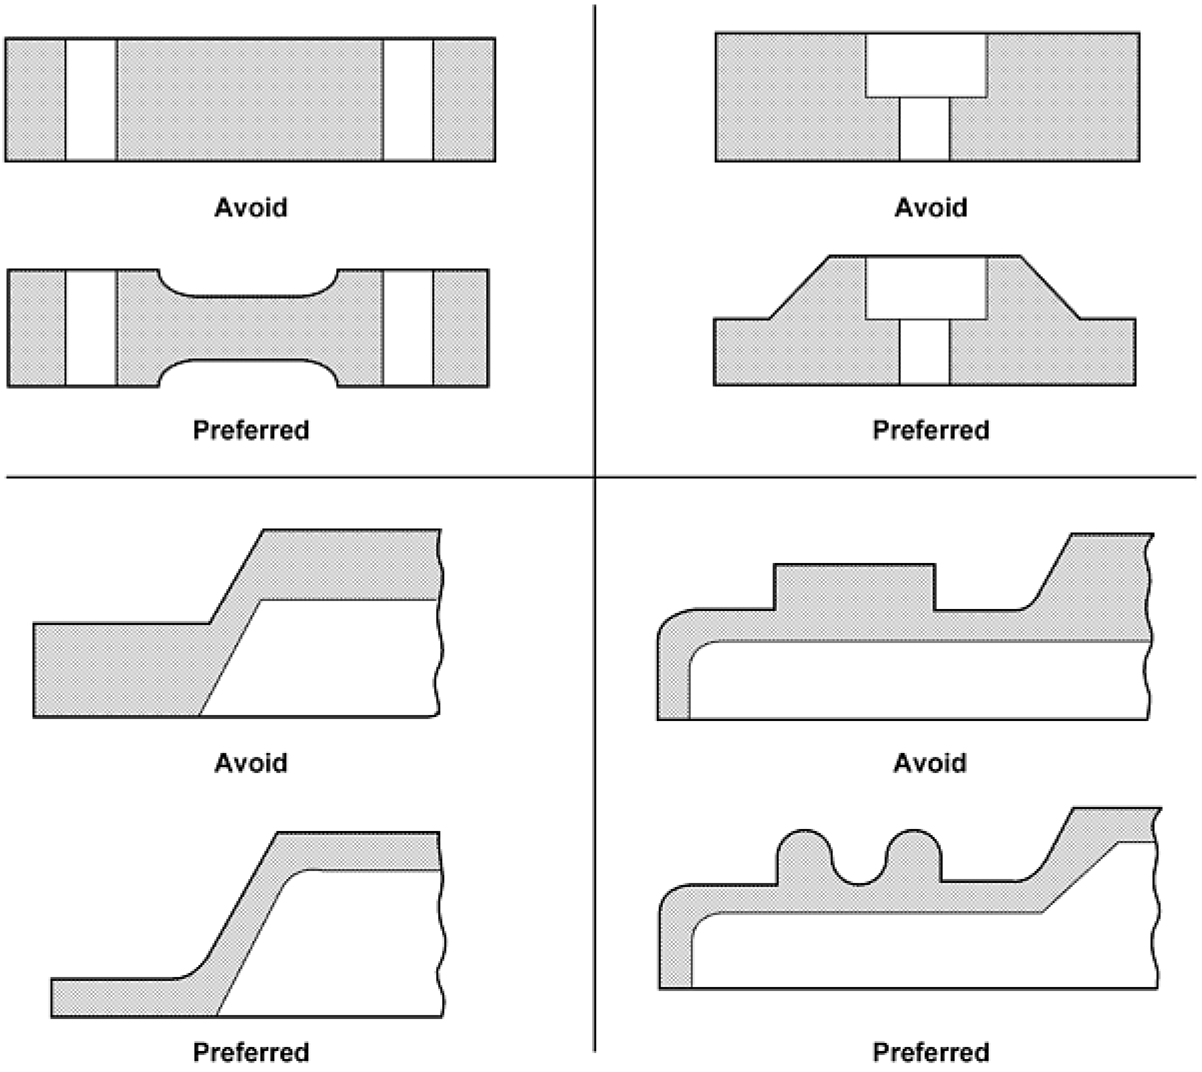

Fig. 15 Designs for maintaining uniform wall thickness in MIM parts. Source: Ref 8

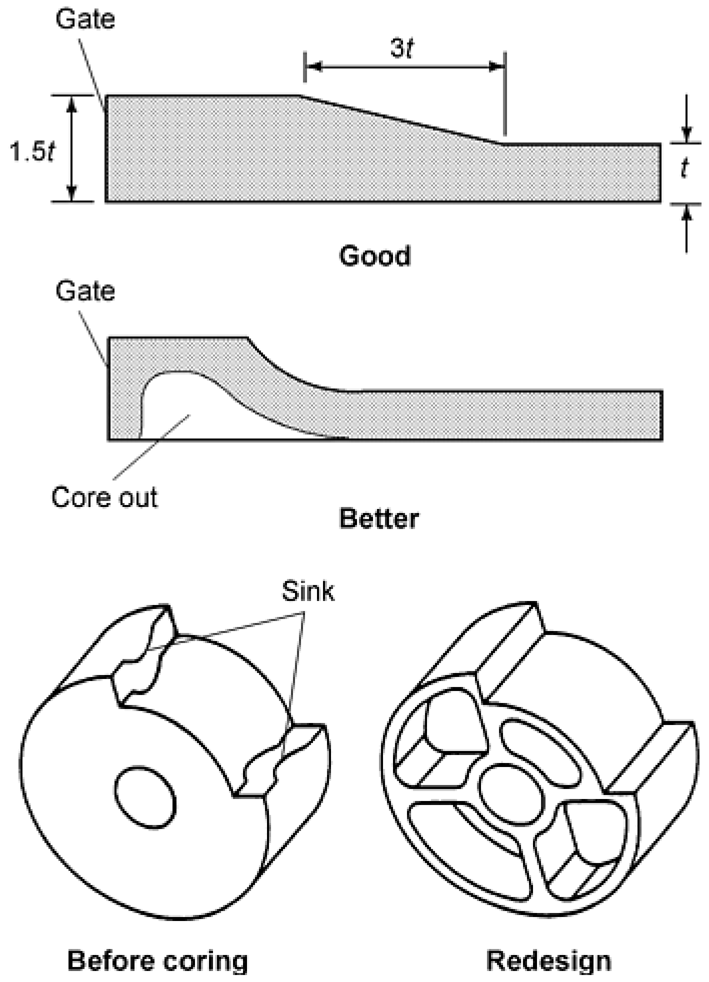

Fig. 16 Redesign of a MIM part to establish uniform wall thickness. Source: Ref 8

Holes should be cored to reduce material usage, promote uniform wall thickness, and reduce or eliminate machining operations. Preferred direction is parallel to the direction of mold opening. Through holes are desired over blind holes. Internally connected holes are possible, preferably perpendicular to each other and, where possible, should be D-shaped, to facilitate core pin sealing and minimize flash (see Fig. 17).

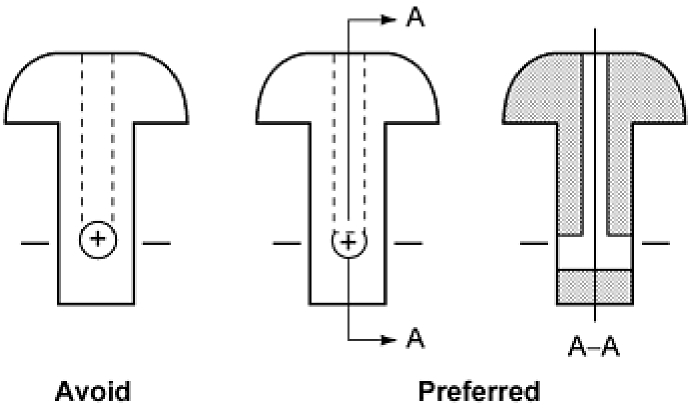

Fig. 17 Intersection holes in MIM parts. Source: Ref 8

Ribs and webs are useful for reinforcing thin walls and avoiding thin sections (Fig. 18). Rib thickness should not exceed that of the adjoining wall. If a thicker rib is required, multiple ribs should be used.

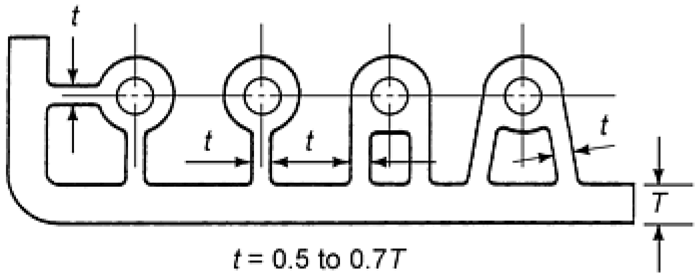

Fig. 18 Design of ribs and webs for MIM parts. Source: Ref 8

Fillets and radii are advantageous to the molding process because they eliminate sharp corners that can cause cracking, distortion, or erosion of mold features. A fillet or radius of 0.40 to 0.75 mm (0.015 to 0.030 in.) is preferred.

Bosses and Studs. The maximum length of a stud or hole should not exceed five times the adjoining wall thickness. A stud diameter should not exceed the thickness of the adjoining wall. A boss with a blind or through hole should have twice the diameter of the hole and a wall thickness not exceeding that of the adjoining surface. As a result, hole diameters are limited to two times the adjoining wall thickness (see Fig. 19).

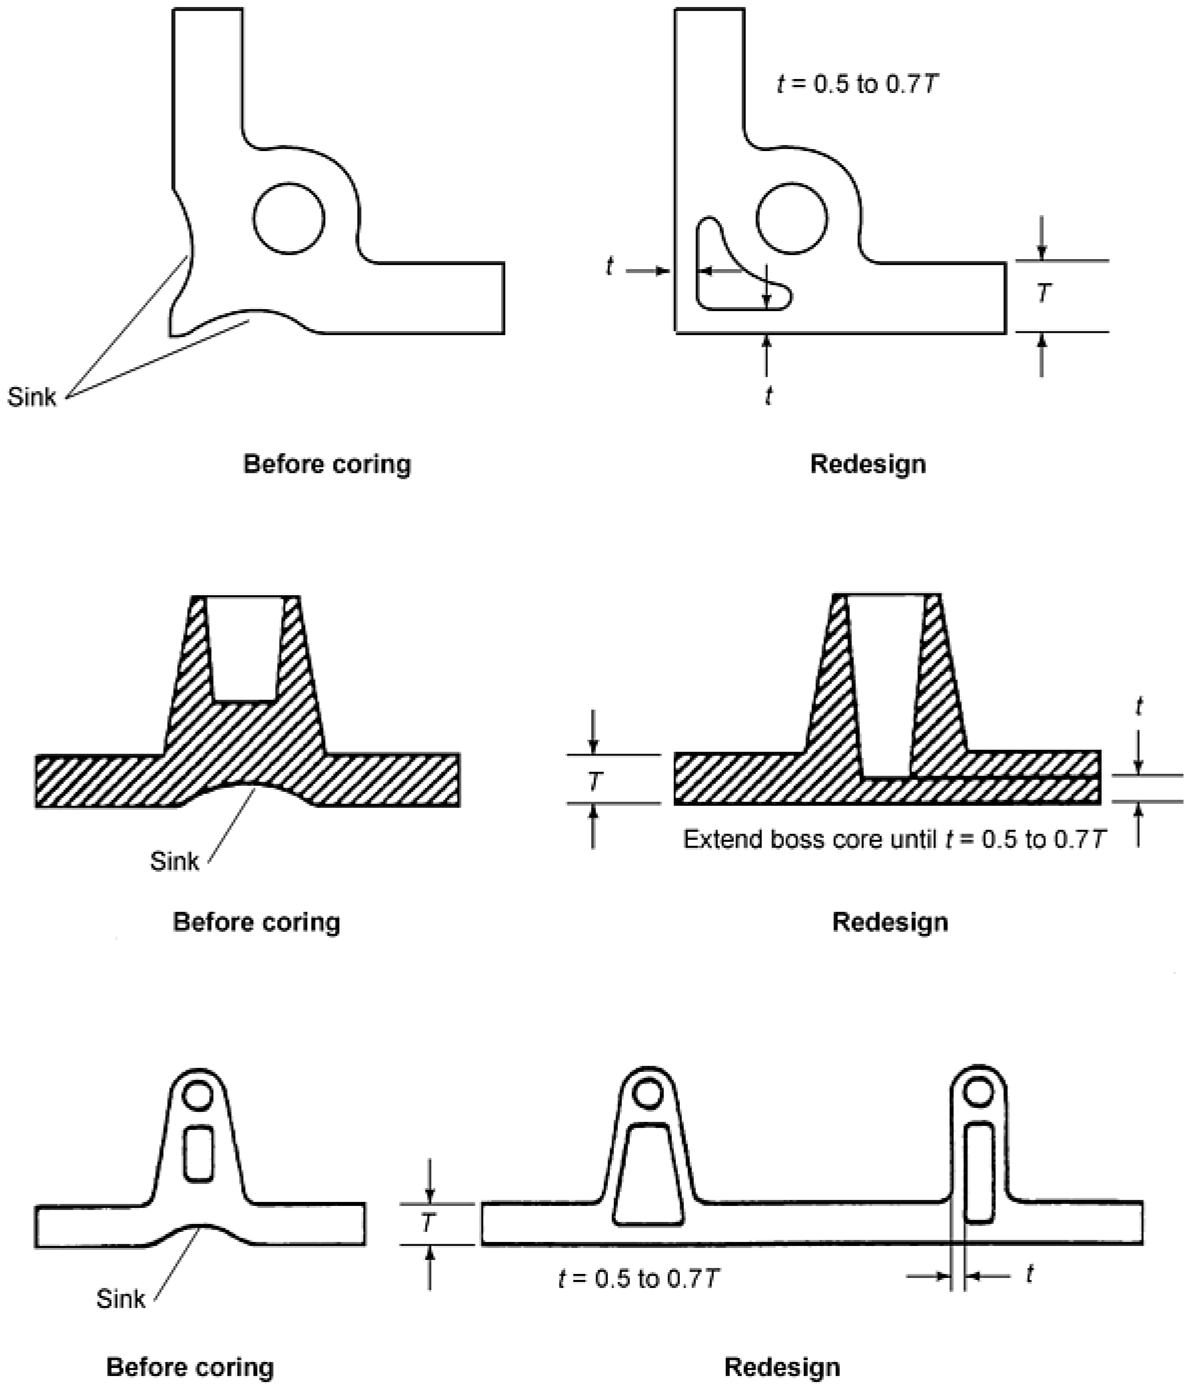

Fig. 19 Design of bosses and studs for MIM parts. Source: Ref 8

Threads. Both internal and external threads can be formed by MIM; however, tapping internal threads is usually more precise and cost effective than forming with core pins that must be unscrewed. Optimal location for external threads is on a parting line (Fig. 20). Adding flats to the threads on the parting surface (Fig. 20) allows for 0.05 mm (0.002 in.) flash, improves thread quality, and reduces mold maintenance.

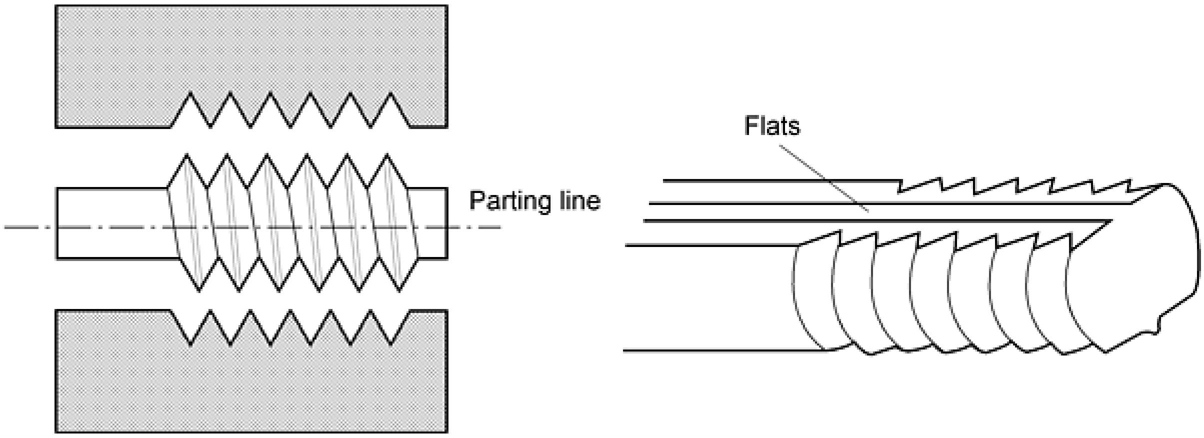

Fig. 20 Design of threads on MIM parts. Source: Ref 8

Undercuts. External undercuts can be formed readily on the parting line. Internal undercuts, though feasible with collapsible cores, are not considered economically practical and should be avoided.

Other features such as knurls, logos, and part numbers can easily be molded in place. The very fine powder size and low porosity produce typical surfaces of 0.8 μm (32 μin.) rms (root mean square) roughness.

Material Selection. The material systems currently in commercial use include ferrous alloys (low-alloy steel, stainless steels, soft magnetic alloys), nonferrous alloys (brass, bronze), tungsten carbide, pure nickel, electronic alloys (Invar, Kovar) and tungsten-copper composites. The physical and mechanical properties of several MIM engineering alloys (low-alloy steel and stainless steels) have been standardized by MPIF (Ref 10). After sintering, the residual porosity in MIM parts is very low and not interconnected. With densities typically in excess of 96% of theoretical density, the resultant mechanical properties are superior to conventional die-compacted P/M materials and more closely match the properties of investment castings in similar alloys. Therefore, the limitations discussed previously regarding the residual porosity in conventional die-compacted products do not apply to MIM parts. Secondary operations can be performed with no restrictions.

Powder Forging

The design issues in powder forging (P/F) are similar to the requirement of any precision, closed-die forging. The difference is the starting preform; in the case of P/F, the preform is a sintered powder metal part, typically 80 to 85% of theoretical density, with a shape similar to the final part configuration. By contrast, in a precision closed-die forging the preform is a wrought steel blank with very little shape detail. Preform design for P/F fabrication determines the extent of product shape detail required to meet the performance requirements of the finished P/F part. Preform design is a complex, iterative process currently modeled by computer simulation software programs to help reduce design time and development costs.

In the forging step, the P/M preform is removed from the reheat (or sintering) furnace, coated with a die lube, and forged in a heated, closed die operation. The forging process reduces the preform height and forces metal into the recesses of the closed die. This step also brings all features to their final tolerances and densities.

Configuration guidelines, typical of precision closed-die forged parts also apply to P/F parts as follows:

- Radii on inside corners of the forging as large as possible to promote metal flow around corners in the tool and promote complete fill of all details.
- Radii of at least 1 mm (0.040 in.) on all outside corners of the forging to aid in material flow to define features.
- Shape of the forging should be such that, when placed in the die, the lateral forces will be balanced. Shapes that are symmetrical along a vertical plane, such as connecting rods and shapes that are

axisymmetric (or nearly so), are preferred.

- Zero draft is possible on surfaces formed by the die and core rod, but not by the upper punch.
- Re-entrant angles (undercuts) cannot be forged.
- Axial tolerances--in the direction of forging--are driven by variations in the mass of metal in the preform. Lateral tolerances are driven by metal flow as the cavity fills. Typical axial tolerance of 0.25 to 0.5 mm (0.010 to 0.020 in.) are encountered, with diametric tolerances of 0.003 to 0.005 mm/mm of diameter.
- Concentricity of a P/F part is determined by the quality and density distribution in the preform. Concentricity is normally double that of the preform.

Design for Machining

D.A. Stephenson, General Motors Powertrain Group

Introduction

MACHINING or material removal processes are secondary manufacturing operations used to achieve precise tolerances or to impart controlled surface finishes to a part. There are three basic classes of machining operations: conventional, abrasive, and nontraditional. *Conventional machining operations* include turning, drilling, milling, boring, planing, shaping, reaming, and tapping. In these operations material is removed from the workpiece in the form of a chip, which for metal parts is produced through plastic deformation. In *abrasive processes,* such as grinding and honing, small particles are removed from the workpiece by abrasion with a hard tool. Abrasive processes have lower material removal rates and higher energy requirements than conventional processes, but can produce closer tolerances and finer surface finishes. *Nontraditional machining processes* include electrodischarge machining (EDM), electrochemical machining (ECM), and ultrasonic machining (USM). In these operations, material is removed by a variety of physical mechanisms, often on an atomic scale with substantially less or no mechanical contact. They tend to remove material much more slowly than conventional or abrasive processes and are generally used when the part geometry or material does not permit the use of any other operation.

Machining operations are costly compared to most other manufacturing processes because they are relatively slow to perform and often require substantial investment in overhead and skilled labor. It has long been known that machining costs can be reduced through proper part design (Ref 1). Many recent books on mechanical design list simple rules that can be used to avoid designing parts with unnecessary machined content or features that are difficult to machine accurately (Ref 2, 3). Although in some cases these lists are overly simplified because they do not take into account part volume and equipment concerns, they indicate a growing awareness of the importance of considering machining issues in the design stage.

This article summarizes rules for designing parts to improve machined part quality and reduce machining costs in mass and batch production environments. Only conventional and abrasive processes such as turning, boring, milling, drilling, and grinding are considered. These processes are described in detail in *Machining,* Volume 16 of *ASM Handbook.* Rules for designing for nontraditional machining operations are discussed in Ref 4.

Machining Costs

As discussed previously, design rules for machining are intended to improve machined part quality and reduce machining costs. Quality issues are discussed below as the various rules are described. The total cost of a machining operation includes contributions from some or all of the following components (Ref 5):

- *Raw material costs:* The cost of unmachined stock, which may be in the form of a standard bar or slab, casting, or forged blank
- *Labor costs:* The wages for the machine operator, usually measured in units of standard hours
- *Setup costs:* The cost of special fixtures or tool setups and the wages paid to setup personnel
- *Tooling costs:* The cost of perishable tooling, including inventory, and any special tooling required for the operation
- *Equipment costs:* The cost of the machine tools, including required capital expenditures, facilities costs, and machine depreciation
- *Scrap and rework costs:* The cost of repairing or disposing of finished or partially finished parts of unacceptable quality
- *Programming costs:* The cost of writing numerical control (NC) programs to generate the required toolpaths
- *Engineering costs:* salaries paid to engineers for process design, validation, and other overhead functions

Design-for-machining rules may address any of the first seven cost categories. The most significant cost component in a given application depends on several factors. Material costs are most significant for parts made of expensive materials or machined from complex castings or forgings. In high-volume production, material, labor, tooling, and scrap costs are generally the most significant. In small- or medium-lot production, setup and programming costs are proportionally more significant. Equipment and tooling costs are of greatest significance when producing complex or precision parts that require special tooling or investment in precision machines. Specific design rules generally have a strong impact on one or a few cost components; therefore, the rules that should be emphasized in a given application vary depending on the complexity of the part, the cost and form of the raw material, and the required production volume.

Engineering costs are generally not reduced through use of design rules for machining; in fact, the application of these rules usually increases overhead as engineering effort is invested up front to realize benefits in later stages of manufacture.

Types of Machining Equipment

Individual machining operations are performed using machine tools. When multiple operations are required to produce a part, they may be performed on a collection of machines arranged as a machining system. Numerous types of machine tools and machining systems are used for different types of parts and production schedules (Ref 5). In applying design-for-machining rules, it is useful to distinguish between three types of machining systems: general-purpose machine tools, production machining systems, and computer numerically controlled (CNC) machining systems.

General-purpose machine tools include lathes, milling machines, drill presses, and similar machines normally found in tool rooms and small job shops. They can perform only a limited range of operations and are used for small batch production of relatively simple parts. The general design-for-machining rules discussed in the next section are applicable to general-purpose machine tools.

Production machining systems (or transfer machines) are complex systems consisting of simpler machine tools connected by an automated material-handling system. They are dedicated systems used for high-volume production of one or a few parts. They operate with a fixed cycle time, during which all operations at a particular station must be completed. The machining time is typically two-thirds to three-quarters of the cycle time for bottleneck operations. Because individual stations in the system resemble conventional machine tools, the general design-for-machining rules discussed in the section "General Design-for-Machining Rules" in this article are broadly valid for these systems. However, due to cycle time restrictions and tool replacement considerations, a number of special design rules also apply, as discussed in the section "Special Considerations" in this article.

Computer numerically controlled machining systems are composed of CNC machining and turning centers operating alone or arranged in cellular or flexible systems. Computer numerically controlled machine tools are capable of a broad range of operations. They can follow tool paths requiring simultaneous motions along several axes and are usually equipped with automatic tool changing systems, so they can often manufacture complex parts with minimal part transfer and refixturing. They are used for medium to large batch production of a variety of parts. As with production machining systems, the general design-for-machining rules discussed in the next section of this article are broadly applicable to these systems. In CNC systems, however, the actual machining time consumes a smaller fraction of the total processing time. Reducing the time required for noncutting functions such as tool changes, axis motions, and pallet rotations thus becomes a priority in operating these systems efficiently, resulting in a number of special design rules as described in the section "Special Considerations" in this article.

Design Considerations. To design a part properly for machining, it is essential to know what kind of equipment will be used to manufacture it. As a first step, the designer should know the type of equipment currently available in the intended manufacturing facility, because design-for-machining rules do not apply equally to all machining systems, and special rules may be critical for certain classes of equipment. The designer should also determine the capabilities (i.e., the range of possible operations and the achievable tolerances) of the available equipment, so that features which will require investment in new or precision equipment can be avoided to the extent possible.

D.A. Stephenson, General Motors Powertrain Group

General Design-for-Machining Rules

The design-for-machining rules discussed in this section are broadly applicable to all parts, regardless of the type of equipment used to produce them.

Choose Materials for Optimal Machinability. Nothing has a greater impact on machining costs and quality than the nature of the work material itself. The nature of the work material determines machining system characteristics such as motor power and bearing sizes, the tool materials and geometries that can be used, the range of cutting speeds and other cutting conditions, the perishable tooling costs, and the tolerances and surface finishes that can be achieved. The material choice is determined largely by material property and other functional requirements independent of machining, but in many cases at least a narrow spectrum of materials is available that satisfy these requirements. When this is the case, the relative machinability of the candidate materials and the standard forms in which each material can be obtained should be considered.

"Machinability" is a loosely defined term reflecting the ease with which materials can be machined (Ref 5, 6). In most cases tool wear rates or tool life under typical conditions are the most significant practical constraints on machining operations, and in practice most tables of machinability ratings are based on tool life test results. For example, a reference material such as 10L14 steel may be assigned a rating of 100, and ratings for other materials are computed from ratios of

tool lives obtained with the material in question and the reference material in a standardized test (Ref 7). Other criteria used to rank material machinability include machining forces and power consumption, chip form, and achievable surface finish.

Machinability varies most significantly between different material classes or base chemistries. The common classes of metallic work materials, in order of decreasing machinability, include:

- Magnesium alloys
- Aluminum alloys
- Copper alloys
- Cast irons
- Nodular irons
- Carbon steels
- Low-alloy steels
- Stainless steels
- Hardened and high-alloy steels
- Nickel-base superalloys
- Titanium alloys

When possible, materials from classes higher on this list should be substituted for those lower on the list, if machinability is a primary consideration.

Machinability generally decreases with increasing penetration hardness and yield strength and with increasing ductility. Homogeneous materials with fine grain structures are easier to machine than nonuniform materials or materials with coarse grain structures. Annealing and tempering also usually increase machinability, although annealed materials are more prone to chip-control problems. Hard alloying elements such as chromium, nickel, and silicon typically reduce machinability. Metal-matrix composites are generally less machinable than the base-matrix metal; similarly, powder metals are less machinable than cast or wrought alloys of equivalent chemistry.

Most material classes include "free-machining" alloys, which contain alloy additives that increase tool life or chip formation characteristics. Free-machining additives are typically substances that form inclusions in the matrix that serve to break chips and provide internal lubrication; examples include lead in brasses and steels, sulfur compounds in steels and powder metals, and insoluble metals such as beryllium, selenium, and tellurium in steels. The addition of free-machining additives often compromises material properties such as hardness or strength; nonetheless, free-machining alloys should be chosen over standard alloys whenever possible to simplify required machining operations.

Minimize the Number of Machined Features. Features should be machined only when they require dimensional or surface finish tolerances that cannot be produced by a primary operation. This is most often the case when the feature in question is used for bearing, locking, locating, press fitting, or dynamic balance, or when subsequent assembly considerations dictate a close dimensional tolerance. Alternative methods of producing features such as casting in holes, chamfers, and undercuts should be considered to minimize the number of machining operations required.

Minimizing the number of machined features reduces machining cycle times, tool costs, and the total number of production operations required to finish a part. To date, elimination of unnecessary machining operations has had a greater practical impact than any of the other design-for-machining rules (Ref 2).

Minimize the Machined Stock Allowance. The amount of material that must be machined away to produce the final part should be minimized. Excessive stock to be removed increases material costs, equipment costs, and fixed tooling costs (since tool wear per part increases with the stock allowance), and increases machining cycle times.

For parts produced from cast or forged blanks, the stock allowance can be controlled by controlling the blank dimensions. Most machined features require roughly 1.5 mm (0.06 in.) of stock for roughing and finishing in two passes. A greater amount of stock should be provided only when primary process tolerances are of this magnitude or when the primary process leaves a thick surface layer of material with unacceptable mechanical properties. An excessively thick surface layer is more likely to occur with cast than with forged blanks. For surfaces with relatively open tolerances requiring only

a single machining pass, the stock allowance should be reduced to 1 mm (0.04 in.) when primary process tolerances permit.

For parts made from bar stock or other standard cold-worked shapes, machined part dimensions should be chosen when possible to be slightly smaller than the dimension of a standard available size. Rotational parts made from cold-rolled steel bars, for example, should have finished diameters roughly 1.25 mm (0.05 in.) smaller than the diameter of a standard bar size. The stock allowance should be increased for larger-diameter bars to account for increased out-of-roundness tolerances in the raw bar. Similarly, if hot-rolled raw stock is used, the machined stock allowance should be increased (to roughly 2.5 mm, or 0.1 in.) to ensure that surface scale is removed.

Optimize Dimensional and Surface Finish Tolerances. The most open dimensional and surface finish tolerances compatible with the part function should be specified for all machined features. Excessively stringent dimensional or surface finish tolerances increase machining costs by requiring the use of additional finishing passes and/or reduced feed rates, which increase machining time, and by dictating more frequent tool changes to avoid the degradation of surface finish that accompanies tool wear.

Figures 1 and 2 (Ref 4) show the range of dimensional and surface finish tolerances that can be achieved using various machining processes under general machining conditions. It is particularly desirable to avoid the use of final grinding and honing operations, as these operations are relatively slow and capital intensive and may produce environmentally hazardous by-products. In general, dimensional tolerances less than 0.025 mm (0.001 in.) and surface finish tolerances less than 0.4 μm (15 μin.) often require the use of grinding or honing operations. (As discussed in the section "Special Considerations" in this article, dimensional tolerances less than 0.05 mm (0.002 in.) can be difficult to achieve consistently without grinding in mass production applications.) Aluminum and magnesium workpieces are generally less likely to require grinding and polishing operations because very fine finishes can be produced through turning and milling with polycrystalline diamond (PCD) tooling.

Size range, mm	Achievable tolerance, ± mm							
0-15	0.004	0.005	0.008	0.013	0.02	0.031	0.051	0.08

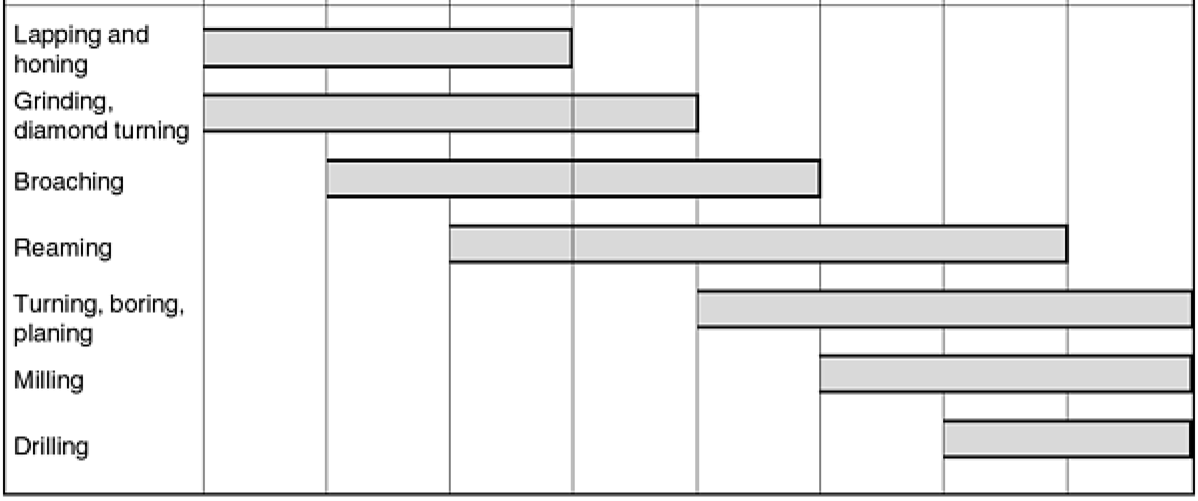

Fig. 1 Dimensional tolerance achievable through various machining operations under general machining conditions as a function of feature size

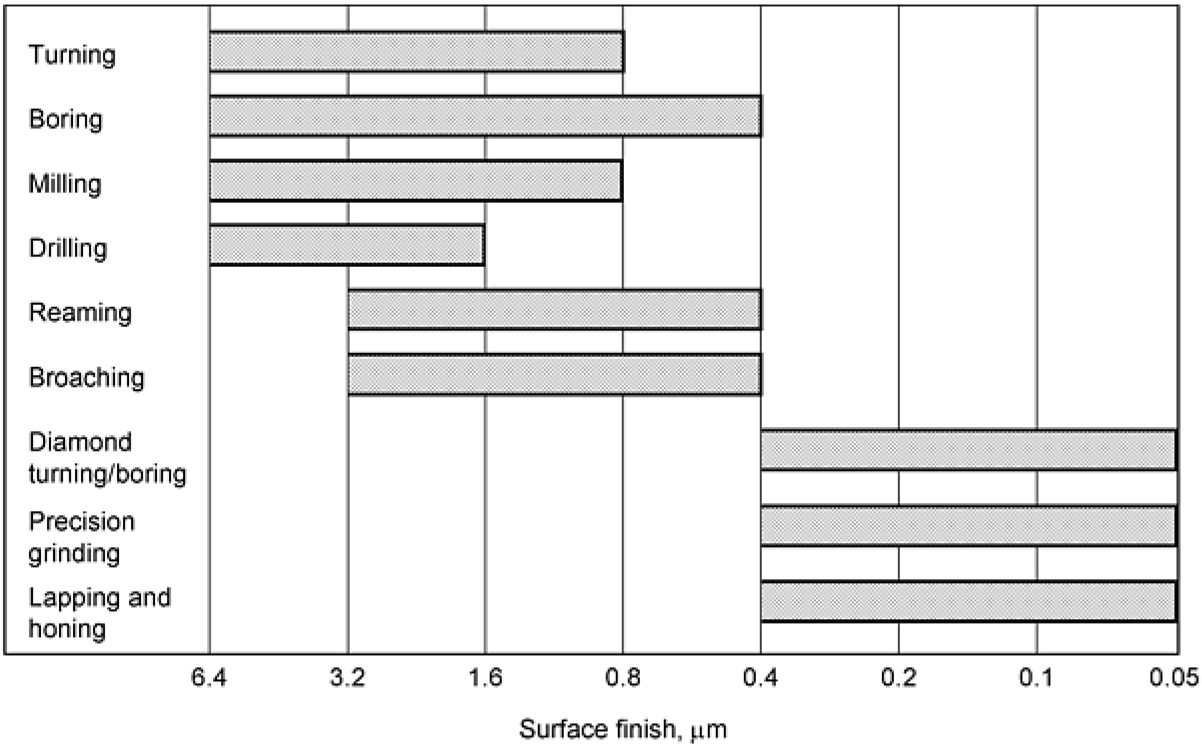

Fig. 2 Surface finish achievable through various machining operations

Standardize Features. Machined features should be standardized to the extent possible. For example, hole diameters should be selected from a limited range of sizes, and the minimum number of different diameters (ideally, one diameter) should be used on a given part. Thread forms should also be standardized based on the hole diameter and work material, and consideration should also be given to standardizing the depth of blind holes based on their intended function. Standardization simplifies and reduces the cost of maintaining a tool inventory. It also promotes interchangeability of tools between operations, reducing the likelihood of tool shortages. As discussed in the section "Special Considerations" in this article, it also reduces the number of tool changes required when CNC equipment is used, reducing machining cycle times.

In standardizing features, dimensions that can be produced from standard rather than special tools should be chosen. This is easily done for hole diameters and tap styles. Internal corner radii used on rotational parts should be chosen to match the nose radii available on standard inserts; this simplifies the CNC programming required to generate radii and reduces the need to stock special inserts.

Minimize the Number of Machined Orientations. Parts should be designed so that the number of machined orientations is minimized. A machined orientation is defined as spatial or directional orientation of a feature with respect to a reference plane or orientation on the part. For example, planes at distinct angles to a reference plane, parallel planes at different depths from a reference position, or holes with axes at different angles to a reference direction (often a normal to a reference plane) can all define distinct machined orientations (Fig. 3).

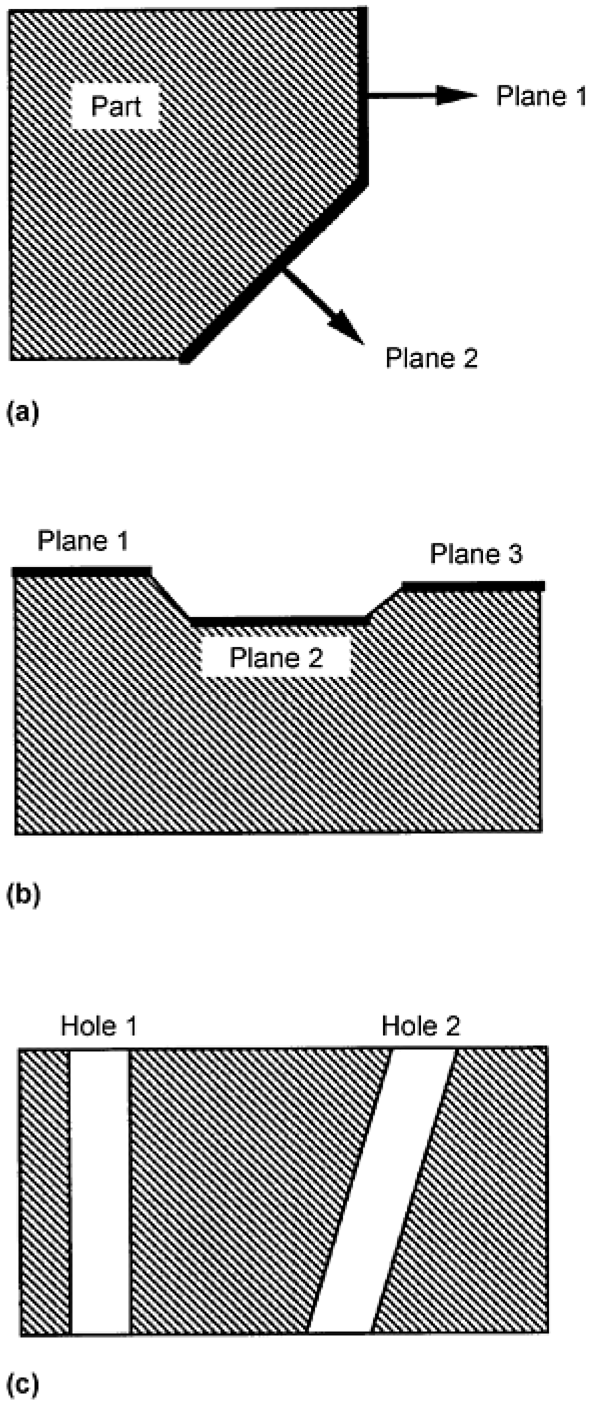

Fig. 3 Examples of features with different machined orientations. (a) Planes with normals in different directions, which may require refixturing or pallet rotations to complete. (b) Parallel planes at different depths, which may require multiple passes, spindle extensions, or tool changes to complete. (c) Holes with axes in different directions, which may require refixturing or pallet rotations to complete

Features with different machined orientations generally cannot be machined with a single tool in a single fixturing or pallet orientation. Therefore, minimizing the number of machined orientations minimizes the number of fixturings, pallet rotations, tool changes, and machining passes required to finish a part. This in turn minimizes processing time and increases machined accuracy.

Provide Adequate Accessibility. In general, a feature becomes more difficult to machine when it becomes more difficult to access with standard tools. Accessibility is most often a problem for features located in internal cavities or on remote faces of the part. Examples of features that should be avoided are shown in Fig. 4 and include increased diameters

in an internal bore, slots and sharp corners at the bottom of a bore, countersinks or counterbores on the exit surfaces of holes (especially when they must be highly concentric), holes on internal surfaces, and surfaces or corners blocked by overhanging features.

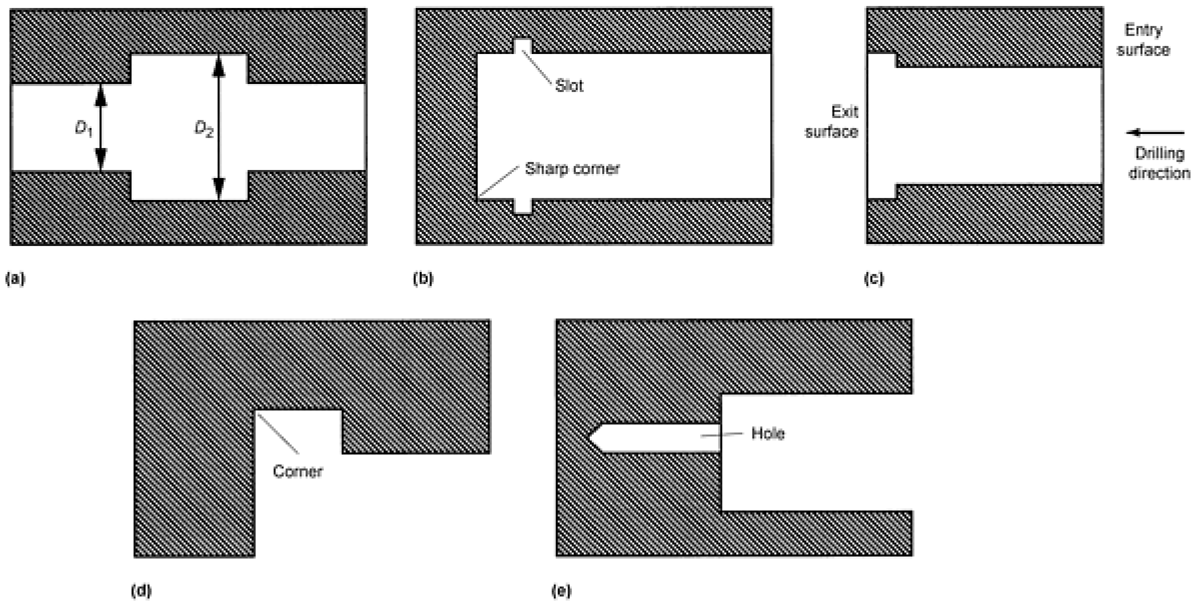

Fig. 4 Machined features that are difficult to access and should be avoided. (a) Increased diameter on an internal bore. (b) A slot and a sharp corner at the bottom of an internal bore. (c) A counterbore on the exit surface of a through hole. (d) A corner blocked by an overhanging surface. (e) A hole on an internal surface

Inaccessible features often require the use of special tooling, tools with long overhangs (length/diameter ratios >5) that may be prone to deflection or unstable vibration, specialized machine attachments such as right-angle drives, or excessive fixturings or pallet rotations. The machining cost is increased, and the achievable tolerance is often limited by these requirements.

Provide Adequate Strength and Stiffness. The cutting forces generated during machining act between the tool and the part and can cause breakage, deflection, or unstable vibrations if the strength and stiffness of the system is inadequate. The part may be the weakest or most compliant element of the system, particularly if it is made of a material such as aluminum--which is relatively weak, a material with a high yield strength and comparatively low elastic modulus such as titanium, or if its geometry is structurally weak.

Care should be taken to design the part so that it has adequate strength and stiffness in the expected directions of loading. This can be done by thickening sections over which heavy loading is expected or by adding ribs or other structurally stiffening features to support thin sections. Because cutting forces increase with the metal removal rate, particular attention should be paid to surfaces that will be subjected to roughing cuts. Thin wall sections and areas where large diameter holes are to be drilled should also be examined and stiffened with ribs or other structural features when possible.

If it is not possible to stiffen the part significantly, cutting forces can be reduced by proper design of the tool and by removing large amounts of stock in multiple passes, although this increases cutting time. Inadequate part stiffness can also be compensated for by designing supporting elements into the fixture, although this significantly increases fixture costs and setup times and reduces the robustness of the process. In extreme cases, stress-sensitive parts may be impossible to machine using conventional operations and may have to be processed using a nontraditional operation such as EDM.

Provide Surfaces for Clamping and Fixturing. Parts must be clamped to a chuck or fixtured securely before they can be machined. In designing a part it is important to consider the possible ways it may be held and to determine if the most likely workholding methods present access problems or part deflection concerns.

Rotational parts are held in lathes between centers or in chucks or collets. Parts finished on both ends and held in chucks or collets must be reversed at some point to complete all required operations. In this case, a clear section of the part with a constant diameter and without a tight surface finish tolerance should be provided for clamping when possible. If this is not possible, an additional grinding operation may be required to produce the part.

Prismatic parts with irregular or curved surfaces may present fixturing difficulties if clamps must be applied to curved surfaces. This can result in point loading and surface deformation or damage, particularly when fixturing for roughing cuts. When possible, clamping pads with flat surfaces should be designed into such parts.

Clamping and fixturing concerns are particularly critical for structurally weak parts, especially when clamping stresses are transmitted through the part (e.g., when the part is held in a vise). In many applications clamping forces exceed machining forces and can contribute significantly to deflections and form errors. Once the principal clamping force directions are determined, the structural stiffness of the part in these directions should be examined, and--if necessary--ribs or other stiffening elements should be added when possible.

Special Considerations

Special Considerations for Production Machining Systems (Transfer Machines). The fixed cycle times and specialized nature of individual mechanisms characteristic of production machining systems result in a number of special design rules for parts manufactured using such systems. In addition, some of the general design-for-machining rules, such as using open tolerances when possible, are more critical for parts made using transfer machines, while other rules, such as maintaining adequate accessibility, are less critical.

Stations on transfer machines can be equipped with multiple spindles, so that patterns of holes can often be drilled simultaneously at a single station. To facilitate this, a minimum separation between holes should be maintained to leave room for distinct spindles. The magnitude of the separation required varies with the hole diameter and the particular type of equipment; for 12 mm (0.5 in.) holes, a minimum separation of 50 mm (2 in.) is typically adequate. Because a single feed slide is normally used on multispindle heads, it is also desirable to make all holes in a given pattern of roughly equal depth; a great variation in depth complicates tool setup and may require an excessive feed stroke length, which can increase cycle time.

Features on parts designed for transfer machine manufacture should be grouped so that multiple features can be machined simultaneously at a single station. Features that require close dimensional tolerances relative to each other should be machined at a single station. When possible, flat surfaces on a given part face should be at equal depths so that all can be machined with a single milling cutter. The amount of stock removed at each station should also be balanced to the extent possible so that all tools wear out at roughly the same time. Light cuts at odd depths that would require additional unbalanced stations should be avoided.

It is more critical to avoid tight tolerances on transfer machine parts than on parts to be manufactured on CNC equipment. The use of tight tolerances that increase the frequency of required tool changes has an exaggerated impact on transfer machine operations, because all or part of a line may need to be shut down to perform a tool change on a single station. Ideally, tools on all stations should be changed on schedule between production shifts to maximize machine utilization. Tolerancing becomes a more critical issue as the machinability of the part material decreases; fairly tight tolerances can be consistently achieved on aluminum and magnesium parts because tool wear rates are low, but it is difficult to achieve dimensional tolerances less than 0.05 mm (0.002 in.) consistently when machining iron or steel parts in high volumes.

Maintaining adequate access to features such as interior holes is not as critical for parts manufactured on transfer machines because special fixtures and jigs (fixtures incorporating guiding components such as bushings) can be more easily incorporated; the additional cost of such jigs and fixtures is more easily justified for the high production runs typical of transfer machines.

Special Considerations for CNC Machining Systems. In operations on CNC machining and turning centers, tools are typically cutting for a smaller fraction of the processing time than in production machining systems; more of the processing time is taken up by noncutting functions such as tool changes, pallet rotations, and axis moves. Most actions that consume noncutting time also have a negative impact on part quality because they introduce additional tolerance components due to the finite accuracy and repeatability of the system. In designing parts to be manufactured on CNC machinery, therefore, the primary concern from a machining viewpoint should be to minimize noncutting functions by appropriate standardization and grouping of features.

Standardizing feature dimensions can reduce the number of required tool changes and thus the processing time. A minimum number of hole diameters should be used on a given part, and holes used for functions such as clearance or mounting should have the same diameter. Care should also be taken to avoid designing in pockets of widely varying dimensions, so that tool changes between end mills of different diameters can be avoided. Standardizing features to eliminate tool changes also simplifies tool magazine management as discussed below.

Pallet rotations can be minimized by reducing the number of machining orientations as discussed in the section "General Design-for-Machining Rules" in this article. Standardizing features reduces axis motion time by eliminating excess tool changes; tool changes consume axis motion time because the spindle or table must generally be moved to a set position for a tool change. In addition to standardizing features, axis motion time can be reduced by reducing the distance between features that must be machined using the same tool. For example, when drilling a pattern of holes with equal diameter, the holes should be placed as close together as possible to minimize transit time between holes. (Note that in this respect hole patterns should be designed differently for parts to be manufactured on NC machines than for those manufactured on transfer machines.)

To further minimize tool changes for medium to long production runs, multidiameter or stepped holes should be designed so that they can be machined using stepped or combination holemaking tools rather than discrete tools as discussed below. The added cost for these special tools is generally not justified for small batch production.

Finally, tool magazine management can be of concern when producing complex parts on CNC machines. Generally, the tool magazine on a CNC machine has a finite capacity (i.e., can hold only a specified number of tools). Some magazine types, such as belt or chain magazines, have a minimum access time to position tools for tool change, and this time often depends on the number of slots between tools used in succeeding operations. Operations should be grouped so that each tool retrieved from the magazine is used for some minimum period greater than the tool access time, so that the machine does not have to wait during the tool access cycle. This becomes a more difficult constraint to satisfy as the access time increases. Parts should be designed so that the number of tools required for the operations scheduled for a given machine does not exceed the number of slots in the tool magazine; if this cannot be arranged, additional time will be required to reload the tool magazine. If the number of slots available exceeds the number of tools required, the surplus slots can be loaded with redundant tools of the type that wear most rapidly, and the NC program can be written to access these additional tools after a specified number of parts have been produced, reducing the number of magazine reloads required. Tool magazine management can be simplified through standardization of features to reduce the number of tools required and through the use of stepped or combination tools to produce multidiameter holes.

Special Considerations for Holemaking Operations. Holemaking operations such as drilling, reaming, and tapping are time-consuming operations often used to produce critical features such as locating holes. As a result, quality issues and machining time constraints are often particularly critical, so that special care should be taken in the design phase to simplify required holemaking operations.

When possible, holes with increased internal diameters, interrupted holes, and holes intersecting inclined entry and exit surfaces should be avoided (Fig. 4a and 5). Holes with increased internal diameters require additional boring operations to produce and cannot be produced using step or compound tools. Holes drilled into inclined entry surfaces or at compound angles often represent unique machined orientations that may require additional fixturings or pallet rotations. It is also more difficult to maintain location accuracy and adequate tool life for these features; the drill has a tendency to "walk" at the entry of such holes, and unbalanced loading that may result in cutting-edge chipping or margin rubbing is also present. Interrupted or intersecting holes also generate unbalanced loads on the drill and may result in straightness errors, excessive vibration, or drill chipping, especially when drilling iron or steel with solid carbide drills. Burrs can also form at intersections, requiring an additional deburring operation. Intersecting holes are often used to produce lubrication passages; when they are unavoidable, an on-center rather than a scalloped design should be chosen (Fig. 6) (Ref 8) to minimize load unbalance, burr formation, and the likelihood that straightness errors will cause the drill to miss the target hole in deep-drilling applications. Drilling through inclined exit surfaces also results in unbalanced loading, which can cause excessive vibration, drill chipping, burr formation, and straightness errors. If such holes are unavoidable, it is advisable to drill them through relatively thick sections of the part (i.e., at depths greater than two drill diameters), so that the initial hole can act as a bushing and support the drill during exit.

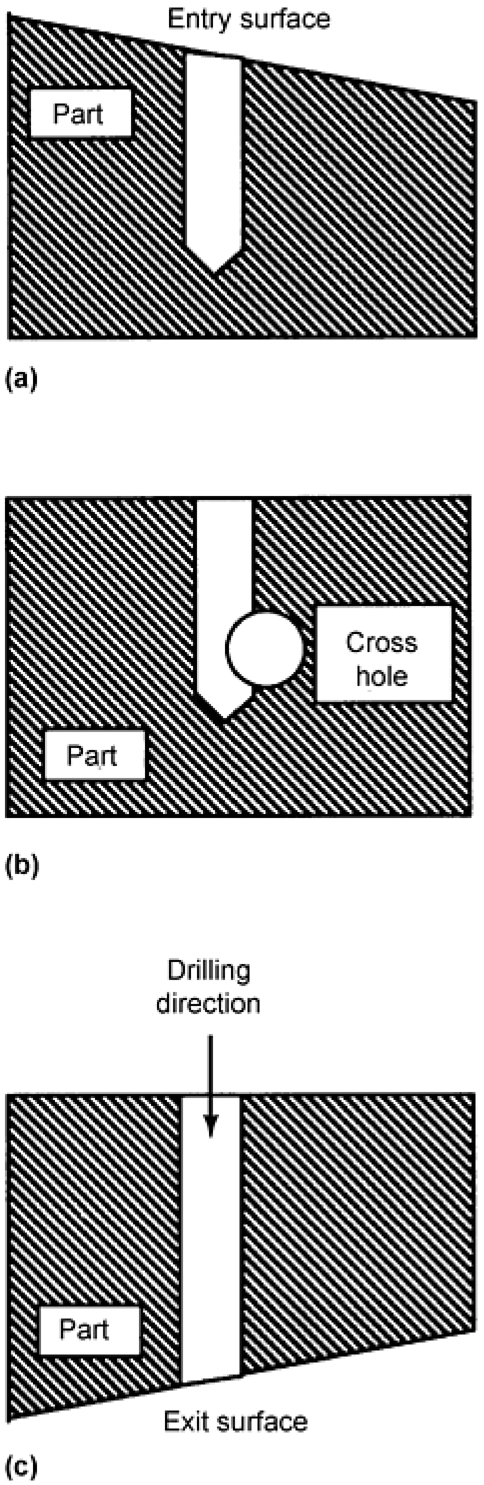

Fig. 5 Examples of hole geometries that should be avoided when possible. (a) A hole drilled into an inclined entry surface. (b) Intersecting holes. (c) A through hole with an inclined exit surface

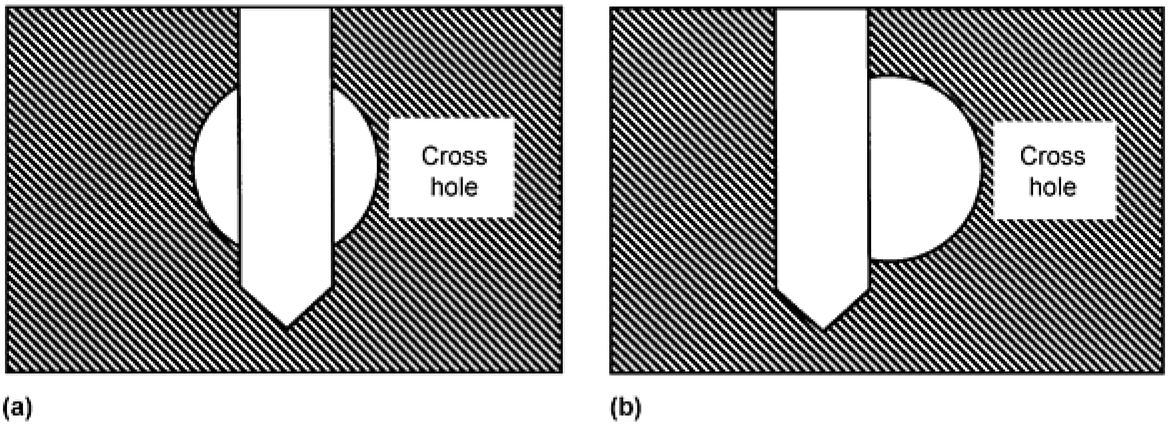

Fig. 6 On-center (a) and scalloped (b) intersecting holes. When intersecting holes are unavoidable, the on-center configuration should be used to minimize drill chipping and burr formation.

For large batch or mass production, multidiameter holes should be designed to be manufactured with step or combination drills rather than discrete drills and counterbores. Specifically, the diameter of such holes should decrease in a stepwise fashion with hole depth, all steps in the hole should have a minimum axial length generally greater than the step diameter, and the difference in the diameters of adjacent steps should not exceed 50% of the larger diameter (Ref 5). As noted above, interior steps with increased diameter (Fig. 3a) require use of a boring bar after drilling and should be avoided, especially when they are greater than three times the drill diameter below the surface. Stepped and combination tools are particularly attractive for CNC equipment because they eliminate tool changes. Cost analyses can be used to determine the conditions under which the additional cost of a stepped or combination tool over discrete standard tools is justified (Ref 5).

Lists of simple design rules often state that blind holes should be avoided (Ref 3). It is often difficult to remove chips from blind holes in parts manufactured on vertical spindle machines, and deep blind holes should be avoided when using such equipment. Blind holes should also be avoided when drilling magnesium parts, because fines that can result in a fire hazard may be generated during spindle reversal at the bottom of such holes. When drilling materials other than magnesium on horizontal spindle equipment, however, the preference for through versus blind holes is not as easily justified. In these applications, chip removal does not present as serious a problem, and the burr formation and additional tool wear generated by vibration and feed surging at exit make through hole drilling less attractive.

Application of Design-for-Machining Rules

Application of the design-for-machining rules requires cooperation between part designers and manufacturing engineers. Ideally this cooperation should begin early in the design process, with the designer consulting with a manufacturing engineer from the intended manufacturing site periodically to develop an understanding of the type and capabilities of the equipment and tooling available at the site, similar information on proposed new equipment purchases, facilities issues, and operating policies that can influence production decisions.

For simple parts, only one designer and a shop foreman or process engineer may be responsible for the part design and manufacturing plan, and communication issues generally do not arise. In large organizations or for complex parts, additional personnel may be involved on both sides. Complicated parts intended for high-volume production may be designed by a team of designers and engineers, and the manufacturing process, tooling, and materials-handling plans may be developed by different manufacturing engineers. In these cases, periodic DFM workshops may be useful in ensuring that input is received from all parties and that decisions are rapidly communicated. These workshops seldom focus on machining issues alone, but also cover manufacturability concerns in casting, assembly, and other operations.

The rules themselves can be applied through various mechanisms (Ref 9). Commonly, they are applied as rules of thumb or incorporated into best practice or design-rule books tailored to the business needs and capabilities of a particular organization. When formal DFM workshops involving a number of participants are held, computer programs such as those described in the section "Computer Aids" in this article can also be used as a supplement to group discussion to help apply the rules in a structured fashion.

Computer Aids

The design-for-machining rules discussed above can be incorporated, at least in simplified forms, into computer programs to aid in automating the design process. These programs may also include tool path generation, functional requirement evaluation, and economic analysis modules to help quantify some of the trade-offs often required to apply the rules, although some subjective input is required to adapt algorithms to the specific application, production volume, and type of equipment under consideration. Two basic types of programs can be used for this purpose: computer-aided process planning (CAPP) and design-for-manufacturing or -manufacturability (DFM) programs. A detailed review of the literature on such programs is beyond the scope of this article; this section briefly describes the structure and typical uses of such programs.

Computer-aided process planning programs (Ref 10, 11, 12, and 13) work with CAD systems to extract the relevant geometric features of a part and produce a process sequence or set of tool paths that is optimal in some sense. Two steps are involved in this approach: feature extraction and optimization. In the feature-extraction stage, the CAD data for the part are analyzed to identify and classify the features that require machining. The extraction algorithm is specific to the CAD system used and particularly to how data are stored and whether the data are parameterized or not. Many systems can be used to classify features. Based on the extraction results, order and precedence constraints are established, and feasible tool paths are generated. The initial tool paths are then refined using an optimization algorithm until a

solution that is optimal according to some criterion is achieved. The simplest criterion is minimum processing or cutting time, although if tool life and economic analyses are performed, a minimum cost criterion can also be used.

Design-for-machining rules and concepts can be applied in principle with CAPP programs as heuristics based on data-extraction results or as constraints based on identified features. Also, if a breakdown of processing time or cost is output as a function of individual features, those features that result in the maximum time or cost can be identified and considered for redesign. The second approach is more straightforward and easily applied.

Computer-aided process planning programs are most easily applied to production with CNC equipment and medium to large production volumes. It is an optimization approach that is normally used at a relatively late stage of the design process when a complete initial design is available.

Design-for-Manufacturability programs (Ref 9, 14) are artificial intelligence programs written specifically to apply DFM rules. General-purpose DFM programs include modules for assembly, stamping, and other processes as well as machining. Because desirable machining practices vary depending on the volume of production and the machine tools available, it is difficult to write a widely applicable general-purpose design-for-machining module. Some large companies have proprietary in-house codes used to apply design-for-machining rules in a manner tailored to their business operations.

A DFM program typically has an input module and an analysis module. Data input is not as automated as in CAPP programs; rather than reading required geometric information from a CAD file, part features and dimensions must generally be input manually according to some format and classification scheme. This is partly because DFM programs are intended to be applied at an earlier stage of the design process (when no complete CAD model of the part may be available), and partly because additional subjective information, such as the perceived relative machinability of various materials or the relative penalty associated with given undesirable features, is often required.

Once data are input, the analysis module is used to compute a relative machinability score for the design as entered. The algorithm used to compute the score varies from program to program, but in general the score depends on the complexity of the design and the penalties associated with difficult-to-machine materials or features. In DFM workshops, some rough estimate of the machining cost can also be computed (e.g., using a spreadsheet) for the given design. The output of the program is a detailed breakdown of components of the score due to individual features, which often clearly identifies the feature(s) most responsible for complexity or excessive cost.

Unlike CAPP programs, DFM programs are used for comparison rather than formal optimization. Usually several design alternatives are compared to a benchmark design, and based on the DFM score the best design is chosen and refined. For complex parts, the process may be repeated at various stages of the design (e.g., at an early stage and before fabrication of the first prototype). Design for manufacturability programs can be used for parts manufactured on either CNC or dedicated production equipment. They are well suited for designing complex parts for mass production and are currently more widely used than CAPP programs in these applications.

Design-for-Machining Examples

Example 1: Redesign of a Shaft Support Bracket.

Figure 7 shows an initial design of a shaft support bracket. This part was designed to be bolted to a mating housing wall to provide support and lubrication for a long shaft. The features to be machined include the shaft bore, an oil hole for lubrication, and mounting holes for dowel pins and bolts. To prevent binding of the shaft, the diameter of the bore must be machined accurately, and the location of the bore center with respect to the dowel pin hole centers must be held to a close tolerance.

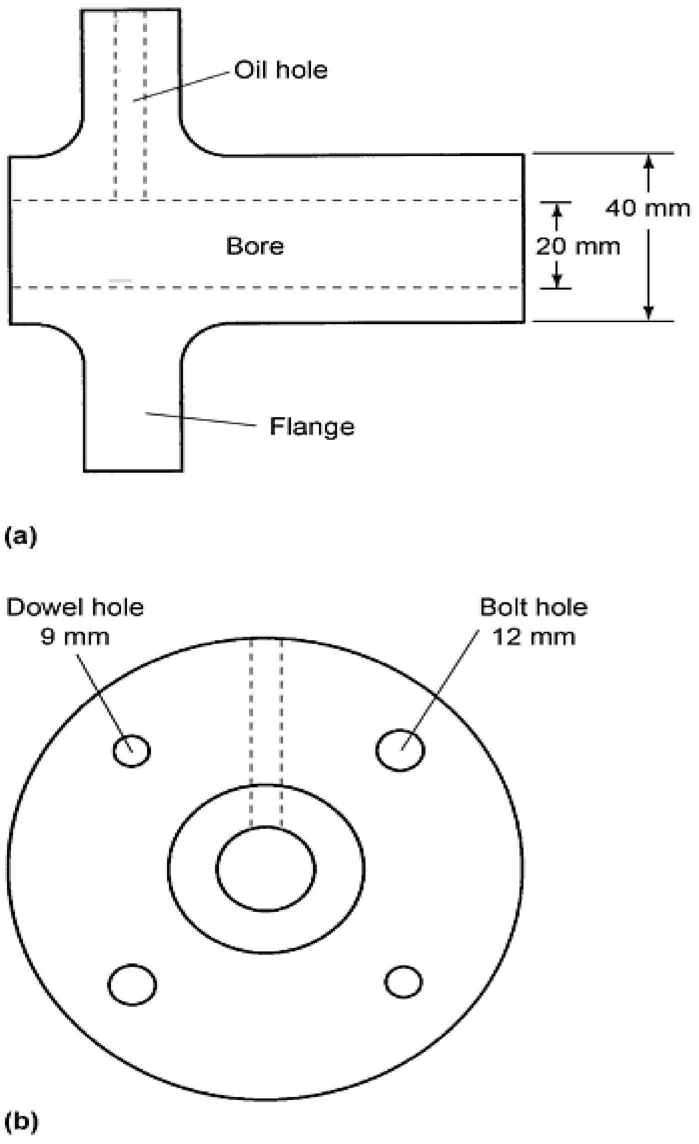

Fig. 7 Side (a) and end (b) views of the initial design for a shaft support bracket

The part, made of nodular cast iron, was to be machined in high volumes on a horizontal spindle CNC machining center. The critical tolerances dictated that the dowel holes be machined first using short drills, and that the bore be produced by a single-point boring bar without refixturing the part.

The initial design presented a number of difficulties from a machining viewpoint. Different diameters were used for the dowel and bolt holes, so that a tool change would be required to produce these features. This would increase processing time and reduce the location accuracy of the holes relative to one another. The bore was long (roughly 100 mm, or 4 in.) and would require a boring step of significant length. The oil hole was also long (roughly 50 mm, or 2 in.) relative to its diameter and would require a long processing step. Finally, there is no obvious way to fixture the part automatically; presumably, it would be held in a vise on the outer surfaces of the flange, which are contoured and would not present flat clamping surfaces. To prevent rotation of the part due to the torques involved in the boring operations, a high clamping pressure would be required; because the clamping stresses are transmitted through the part, this could result in distortion of the bore and an out-of-roundness error upon unclamping.

The part was redesigned to address these difficulties as shown in Fig. 8. Three significant changes were made. First, the diameters of the dowel and bolt holes were standardized to eliminate the tool change. Second, the casting was changed so that the center of the bore had a larger diameter than the ends. This increased the mass of the part, but reduced the length of the bore, which would have to be machined to roughly 40 mm (1.6 in.). In addition, the depth of the oil hole was reduced by 5 mm (0.2 in.), and the hole no longer exited on a machined portion of the bore, eliminating a possible exit burr condition. Finally, flat surfaces were cast on three faces of the flange to provide clamping pads and to eliminate a contoured entry surface when drilling the oil hole. The revised part could easily be fixtured by clamping in a vise on the flat surfaces parallel to the oil hole; by mounting the vise on an angle plate on the machine table, the hole could be drilled horizontally from the side of the vise. A lower clamping pressure could be used because the flats provide a positive stop that would resist rotation. The flat surface provided for the oil hole entry also reduced the hole depth by an additional 5 mm (0.2 in.).

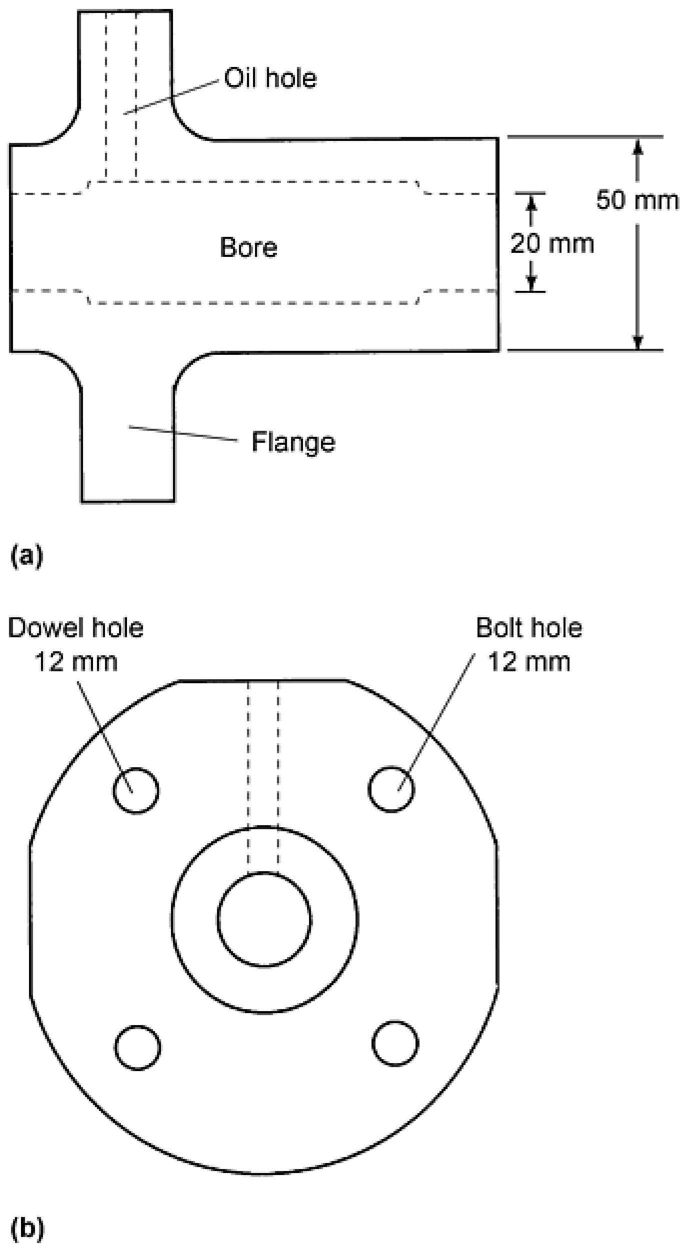

Fig. 8 Side (a) and end (b) views of a shaft support bracket redesigned to simplify machining

With these changes, the processing time required to machine these features was reduced from 173 to 119 s, a reduction of more than 33%; in addition, the design changes should improve part quality by simplifying achievement of the critical tolerances and by permitting the use of reduced clamping pressures.

Example 2: Redesign of a Rotor Housing.

Figure 9 shows a cross section of the initial design of a die-cast aluminum rotor housing to be machined in several steps on CNC turning centers. In the operation shown, internal surfaces are to be cut using boring and grooving tools. To minimize axial tolerances between normal surfaces, two long boring passes (labeled "first cut" and "second cut" in Fig. 9) are planned. In addition, two grooves for retaining rings are also required.

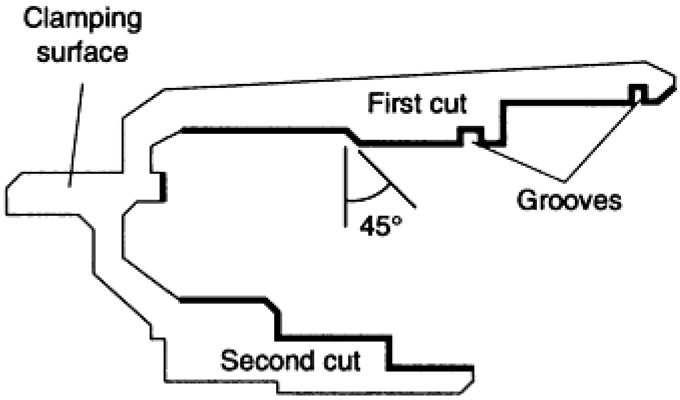

Fig. 9 Cross section of the initial design for a rotor housing

The boring passes are difficult to plan for the initial design. There are several internal sharp corners; in addition, there is an internal angled cut at 45° to the part axis which cannot be accessed by a standard tool that will clear other internal surfaces. The grooves also have different axial widths. For the initial design, therefore, two grooving tools, two standard boring tools, and additional special tools to reach the internal sharp corners would be required to make the desired cuts.

Figure 10(a) shows a revised design that simplifies the machining. Upon consultation, it was determined that the dimensions of the grooves could be standardized, eliminating the need for one of the grooving tools. The internal sharp corners were replaced by radiused corners to permit machining with a standard boring insert. Finally, the initial 45° angled cut was replaced with a 60° angled cut that could be produced with a standard 55° boring insert mounted in a standard -5° lead boring bar as shown in Fig. 10(b). In the revised design, the required cuts can be made with two standard boring tools and a single grooving tool, saving at least three tool changes. Because the special tools required to machine the sharp internal corners would wear rapidly, the revised design also results in increased tool life and improved part quality.

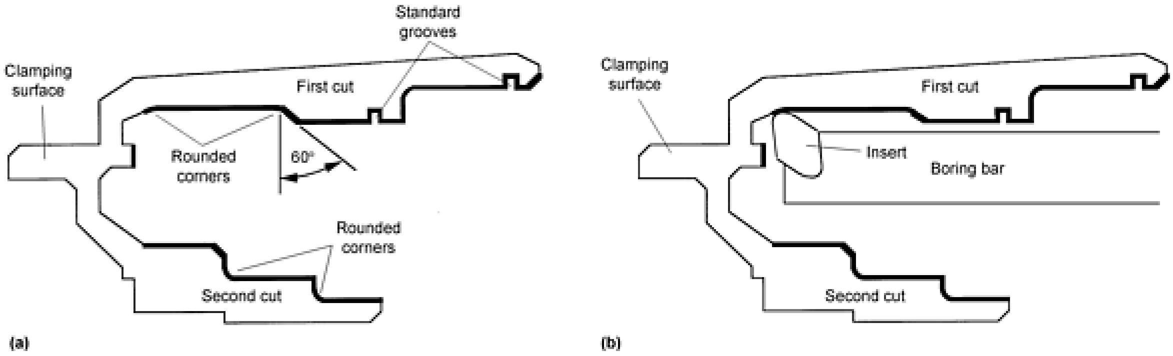

Fig. 10 (a) Cross section of a rotor housing redesigned to simplify machining. (b) Access to internal features using a boring bar with a standard 55° boring insert

Design for Joining

K. Sampath, Concurrent Technologies Corporation

Introduction

JOINING is an important manufacturing activity employed in assembling parts to make components. The individual parts of a component meet at *joints.* Joints primarily transmit or distribute forces generated during service from one part to the other parts of an assembly. A joint can be either temporary or permanent. Commonly, five joint types are used in the joining of parts: butt, tee, corner, lap, and edge (Fig. 1).

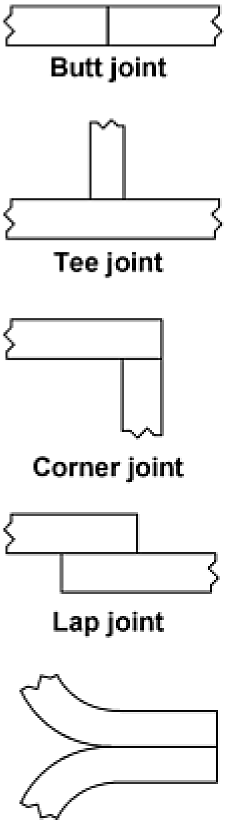

Fig. 1 Types of joints. Source: Ref 1

The selection of an appropriate design to join parts is based on a concurrent understanding of several considerations related to product and joining process. Product-related considerations include codes and standards, fitness for service, aesthetics, manufacturability, repairability, reliability, inspectability, safety, and unit cost of fabrication. Considerations related to joining process include material types and thicknesses, joint (part) geometry, joint location and accessibility, handling, jigging and fixturing, distortion control, productivity, and initial investment. Additional considerations include whether the joint is fabricated in a shop or at a remote site, possibilities for premature failure, and containment in case of a catastrophic failure (this is applicable, for example, to components subjected to nuclear radiation).

The term *joint design* emphasizes designing of a joint based on product-related considerations for meeting structural design requirements. The design or selection of appropriate joint type is determined primarily from the type of service loading. For example, butt joints are preferred over tee, corner, lap, or edge joints in components subjected to fatigue loading. The specific joint design aspects, such as the size, length, and relative orientation of the joint, are based on stress calculations that are derived from an evaluation of service loads, properties of materials, properties of sections, and appropriate structural design requirements. An ideal joint is one that effectively transmits forces among the joint members and throughout the assembly, meets all structural design requirements, and can still be produced at minimal cost (Ref 1). Individual articles in various Sections of this Volume specifically address design of parts or components based on an understanding of several product-related considerations vis-à-vis appropriate structural design requirements.

The term *design for joining* refers to creating a mechanism that allows the fabrication of a joint using a suitable joining process, at minimal cost. In this context, design for joining emphasizes how to design a joint or conduct a joining process so that components can be produced most efficiently and without defects. This involves selection and application of good design practices based on an understanding of process-related manufacturing aspects such as accessibility, quality, productivity, and overall manufacturing cost. This article provides a brief description of various joining processes, a summary of good design practices from a joining process standpoint, and several examples of selected parts and joining processes to illustrate or highlight the advantages of a specific design practice in improving manufacturability.

Design for Joining

K. Sampath, Concurrent Technologies Corporation

Joining Processes

Joining processes include mechanical fastening, adhesive bonding, welding, brazing, and soldering. Mechanical fastening and adhesive bonding are often (but not always) used to produce temporary or semi-permanent joints, while welding, brazing, and soldering processes are used to provide permanent joints. Mechanical fastening and adhesive bonding usually do not cause metallurgical reactions. Consequently, these methods are preferred when joining dissimilar combinations of materials, and for joining metal-matrix, ceramic-matrix, and polymer-matrix composites that are sensitive to metallurgical phase changes or polymerization reactions.

Mechanical Fastening (Ref 2). The selection and satisfactory use of a particular fastener are dictated by the design requirements and conditions under which the fastener will be used. Consideration must be given to the purpose of the fastener, the type and thickness of materials to be joined, the configuration and total thickness of the joint to be fastened, the operating environment of the installed fastener, and the type of loading to which the fastener will be subjected in service.

Threaded fasteners are considered to be any threaded part that, after assembly of the joint, may be removed without damage to the fastener or to the members being joined.

Rivets are permanent one-piece fasteners that are installed by mechanically upsetting one end.

Blind fasteners are usually multiple-piece devices that can be installed in a joint that is accessible from only one side. When a blind fastener is being installed, a self-contained mechanism, an explosive, or other device forms an upset on the inaccessible side.

Pin fasteners are one-piece fasteners, either solid or tubular, that are used in assemblies in which the load is primarily shear. A malleable collar is sometimes swaged or formed on the pin to secure the joint.

Special-purpose fasteners, many of which are proprietary, such as retaining rings, latches, slotted springs, and studs, are designed to allow easy, quick removal and replacement and show little or no deterioration with repeated use.

Adhesive Bonding (Ref 3). An adhesive is a substance (usually an organic or silicone polymer) capable of holding materials together in a functional manner by surface attachment. The capability of holding materials together is not an intrinsic property of a substance but, rather, depends on the context in which that substance is used. Two important, basic facts about adhesive materials are that a substance called an adhesive does not perform its function independent of a context of use and that an adhesive does not exist that will bond "anything to anything" with (implied) equal utility.

The major function of adhesives is for mechanical fastening. Because an adhesive can transmit loads from one member of a joint to another, it allows a more uniform stress distribution than is obtained using a mechanical fastener. Thus, adhesives often permit the fabrication of structures that are mechanically equivalent or superior to conventional assemblies and, furthermore, have cost and weight benefits.

Although the major function of adhesives is to fasten, sometimes they are also required to seal and insulate. Formulations that are good electrical and/or thermal conductors are also available. Further, adhesives prevent electrochemical corrosion in joints between dissimilar metals and resist vibration and fatigue. In addition, unlike mechanical fasteners, adhesives do not generally change the contours of the parts that they join.

Detailed information on adhesives and adhesive bonding is available in *Adhesives and Sealants,* Volume 3 of the *Engineered Materials Handbook* published by ASM International.

Welding includes both fusion welding and solid-state welding processes.

Fusion welding processes involve localized melting and solidification and are normally used when joining similar material combinations or materials belonging to the same family (e.g., joining one type of stainless steel with another type). Figure 2 illustrates the type of welds commonly used with fusion welding processes such as arc welding (Ref 1).

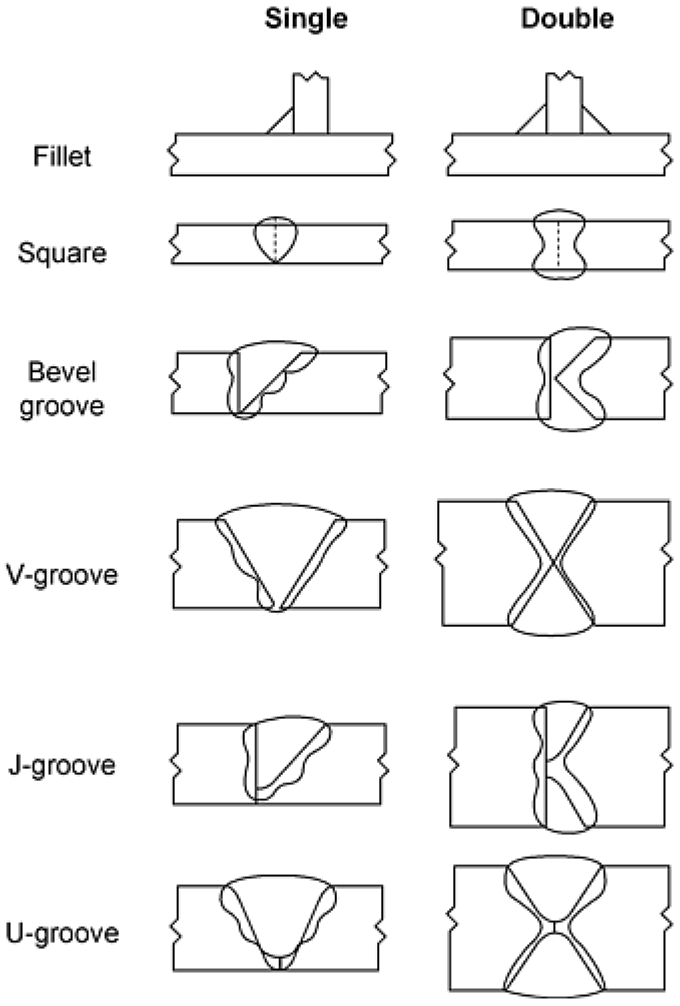

Fig. 2 Types of welds. Source: Ref 1

Fusion welding processes also include electron beam welding and laser welding. These two welding processes require precise joint gap and positioning. Joint designs and clearances that overwhelmingly trap the beam energy within the joint cavity are preferred for increasing process efficiency. Figure 3 shows preferred and non-recommended joint designs for electron beam welding (Ref 4). When joining thick sections, the preferred joint designs allow the weld metal to freely shrink without causing cracking.

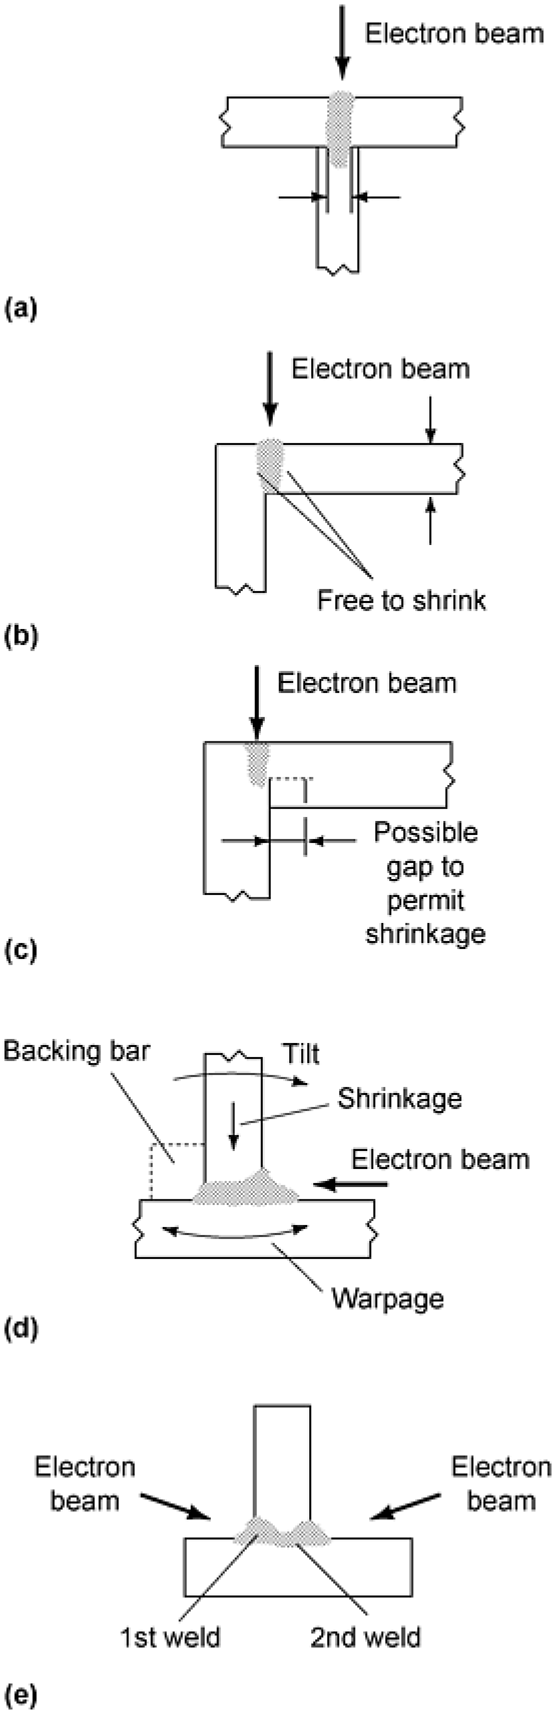

Fig. 3 Optimum versus least desirable weld configurations. (a) Not recommended--maximum confinement of molten metal, minimum joining cross section (arrows); wastes beam energy for melting, nonfunctional metal. (b) Most favorable--volume of melt not confined; maximum joining cross section (arrows). (c) Not recommended--maximum confinement of melt (unless gap is provided); joining cross section less than plate cross section. (d) Most favorable--minimum constraint and confinement of melt; minimum internal stresses; warpage can be offset by bending prior to welding; tilt can be offset by location of T-arm at less than 90° to

base prior to welding. Fillet obtained by placing wire in right corner and melting it with the beam. (e) Not recommended--two successive welds; second weld is fully constrained by the first weld and shows strong tendency to crack. Source: Ref 4

Solid-state welding processes preclude melting and solidification and therefore are suitable for joining dissimilar materials. However, the process conditions may allow solid-state metallurgical reactions to occur in the weld zone. When metallurgical reactions occur, they can either benefit or adversely affect the properties of the joint. From a metallurgical perspective, the application of both fusion welding and solid-state welding processes must be evaluated using appropriate weldability testing methods for their ability to either *recreate* or *retain* base metal characteristics across the joint. These weldability evaluations combine material, process, and procedure aspects to identify combinations that would provide a weld joint with an acceptable set of properties.

Solid-state welding processes also have special joint design or part cross-section requirements. For example, continuous-drive and inertia friction welding processes require that one of the parts exhibit a circular or near-circular cross section. Diffusion bonding is another solid-state welding process that allows joining of a variety of structural materials, both metals and nonmetals. However, diffusion bonding requires an extremely smooth surface finish (8 μm) to provide intimate contact of parts, a high temperature, and a high pressure, first to allow intimate contact of the parts along the bond interface, followed by plastic deformation of the surface asperities (on a microscopic scale), and second to promote diffusion across the bond interface. The need to apply pressure while maintaining part alignment imposes a severe limitation on joint design.

Alternatively, when exceptional surface finish is difficult to achieve, a metallurgically compatible, low-melting interlayer can be inserted between the parts to produce a transient liquid phase on heating. On subsequent cooling this liquid phase undergoes progressive solidification, aided by diffusion across the solid/liquid interfaces, and thereby joins the parts. This process has characteristics similar to those of the brazing process.

Brazing (Ref 5, 6) is a process for joining solid metals in close proximity by introducing a liquid metal that melts above 450 °C (840 °F). A sound brazed joint generally results when an appropriate filler alloy is selected, the parent metal surfaces are clean and remain clean during heating to the flow temperature of the brazing alloy, and a suitable joint design that allows capillary action is used.

Strong, uniform, leakproof joints can be made rapidly, inexpensively, and even simultaneously. Joints that are inaccessible and parts that may not be joinable at all by other methods often can be joined by brazing. Complicated assemblies comprising thick and thin sections, odd shapes, and differing wrought and cast alloys can be turned into integral components by a single trip through a brazing furnace or a dip pot. Metal as thin as 0.01 mm (0.0004 in.) and as thick as 150 mm (6 in.) can be brazed.

Brazed joint strength is high. The nature of the interatomic (metallic) bond is such that even a simple joint, when properly designed and made, will have strength equal to or greater than that of the as-brazed parent metal.

The mere fact that brazing does not involve any substantial melting of the base metals offers several advantages over other welding processes. It is generally possible to maintain closer assembly tolerances and to produce a cosmetically neater joint without costly secondary operations. Even more important, however, is that brazing makes it possible to join dissimilar metals (or metals to ceramics) that, because of metallurgical incompatibilities, cannot be joined by traditional fusion welding processes. (If the base metals do not have to be melted to be joined, it does not matter that they have widely different melting points. Therefore, steel can be brazed to copper as easily as to another steel.)

Brazing also generally produces less thermally induced distortion, or warping, than fusion welding. An entire part can be brought up to the same brazing temperature, thereby preventing the kind of localized heating that causes distortion in welding.

Finally, and perhaps most important to the manufacturing engineer, brazing readily lends itself to mass production techniques. It is relatively easy to automate, because the application of heat does not have to be localized, as in fusion welding, and the application of filler metal is less critical. In fact, given the proper clearance conditions and heat, a brazed joint tends to "make itself" and is not dependent on operator skill, as are most fusion welding processes.

Automation is also simplified by the fact that there are many means of applying heat to the joint, including torches, furnaces, induction coils, electrical resistance, and dipping. Several joints in one assembly often can be produced in one multiple-braze operation during one heating cycle, further enhancing production automation.

Soldering (Ref 7) is a joining process by which two substrates are bonded together using a filler metal (solder) with a liquidus temperature that does not exceed 450 °C (840 °F). The substrate materials remain solid during the bonding process. The solder is usually distributed between the properly fitted surfaces of the joint by capillary action.

The bond between solder and base metal is more than adhesion or mechanical attachment, although these do contribute to bond strength. Rather the essential feature of the soldered joint is that a metallurgical bond is produced at the filler-metal/base-metal interface. The solder reacts with the base metal surface and wets the metal by intermetallic compound formation. Upon solidification, the joint is held together by the same attraction, between adjacent atoms, that holds a piece of solid metal together. When the joint is completely solidified, diffusion between the base metal and soldered joint continues until the completed part is cooled to room temperature. Mechanical properties of soldered joints, therefore, are generally related to, but not equivalent to, the mechanical properties of the soldering alloy.

Mass soldering by wave, drag, or dip machines has been a preferred method for making high-quality, reliable connections for many decades. Correctly controlled, soldering is one of the least expensive methods for fabricating electrical connections.

Advantages of brazing and soldering include the following:

- The joint forms itself by the nature of the flow, wetting, and subsequent crystallization process, even when the heat and the braze or solder are not directed precisely to the places to be joined.
- The process temperature is relatively low, so there is no need for the heat to be applied locally, as in welding.
- Brazing and soldering allow considerable freedom in the dimensioning of joints, so that it is possible to obtain good results even if a variety of components are used on the same product.
- The brazed or soldered connections can be disconnected if necessary, thus facilitating repair.
- The equipment for both manual and machine brazing/soldering is relatively simple.
- The processes can be easily automated, offering the possibility of in-line arrangements of brazing/soldering machines with other equipment.

K. Sampath, Concurrent Technologies Corporation

Basic Design Considerations

When designing a joint, one should initially consider manufacturability of the joint, whether at a shop or at a remote site. For example, consider the need for a high integrity, high-performance joint between two dissimilar materials such as a low-carbon steel and an aluminum alloy. If this joint has to be produced at a remote site, the available choice of joining processes is extremely limited. A viable alternative would be to produce at a shop a transition piece involving the two dissimilar materials. Using controlled process conditions at a shop, one could produce a high-integrity transition piece using one of the solid-state welding processes. The selection of the appropriate solid-state welding process would depend on joint (part) geometry. A transition joint between a plate and a pipe is best produced using a friction welding process, while a joint between two large plate surfaces is best produced using explosive bonding. Because these joining processes preclude melting and solidification, they provide high-integrity joints free from porosity or solidification-related defects. Transition pieces so produced could be used at a remote site to make similar metal joints between component parts with no undue quality assurance or quality control concerns.

Design for Joining

K. Sampath, Concurrent Technologies Corporation

Good Design Practices

A joint must be designed to benefit from the inherent advantages of the selected method of joining. For example, braze joints perform very well when subjected to shear loading, but not when subjected to pure tensile loading. When using a brazing process to join parts, it would be beneficial to employ innovative design features that would convert a joint subjected to tensile loading to shear loading. For example, use of butt-lap joints instead of butt joints can provide a beneficial effect in flat parts and tubular sections.

Joints must be designed to reduce stress concentration. Sharp changes in part geometry near the joint tend to increase stress concentration or notch effects. Smooth contours and radiused corners tend to reduce stress concentration effects. Figure 4 shows a number of ways to redistribute stresses in a brazed joint (Ref 8).

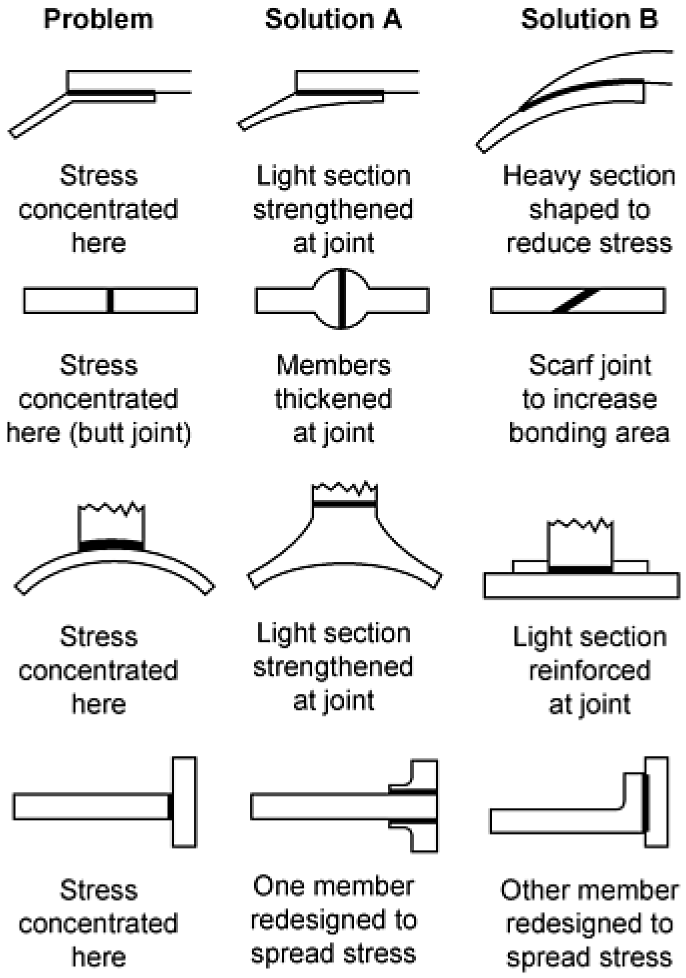

Fig. 4 Design of a brazed joint to redistribute stress. Source: Ref 8

When determining appropriate joint designs, one should initially consider standard or recommended joint designs. In practice, several standard joint designs may be suitable for producing a joint. Subtle or innovative features could be added to the recommended joint designs to improve productivity through mechanization or automation, to enhance joint performance, and to ensure safety.

Orientation and Alignment. Design features that promote self-location and maintain the relative orientation and alignment of component parts save valuable time during fit-up and enhance the ability to produce a high-quality joint. For example, operations involving furnace brazing or diffusion bonding with interlayers benefit from such a type of joint design, because they also require pre-placement of the brazing filler or the interlayer in the joint.

The pin-socket type of temporary joints in modern electrical, telephone, and computer connectors allow temporary joining of cables in only one way. These joint designs strongly discourage any inadvertent misalignment or wrong orientation of the connectors and thereby eliminate a variety of hazards. The snap-on interlocking features in twisted, threaded, or non-threaded adapter joint designs, commonly used in children's toys, often allow the snapping sound of a latch to indicate the satisfactory completion of the joint and its safety for the intended use.

Jigging and fixturing can also be used to maintain relative orientation of parts. When necessary, the fixturing devices should be designed for the least possible thermal mass and pin-point or knife-line contact with the parts. Fixtures of low thermal mass and minimal contact with the parts reduce the overall thermal load during joining. Further, arc welding processes generally allow higher deposition rates when joining is performed in the downhand position, where gravity effects tend to support a large volume of molten weld metal at the joint region. When joining parts that exhibit a nonplanar joint contour, positioning equipment can be used to continuously manipulate the parts so that the welding is performed in the downhand position. In such cases, the design of the joint and fixtures should be complementary to the positioning equipment used, and it should not interfere with the functioning of the positioning equipment.

Joint Location and Accessibility. From a structural integrity standpoint, joint locations should be chosen such that they are not in regions subjected to maximum stress. Concurrently, joints must be placed in locations that will allow operators to readily make the joints using the selected method of joining. Figure 5 illustrates the effect of location of a joint on accessibility (Ref 1). Limited accessibility can reduce the overall quality of the joint, decrease productivity, or both. Invariably, limited accessibility to produce joints also limits accessibility to perform nondestructive evaluation of joint quality, either during the time the joint is made or afterwards.

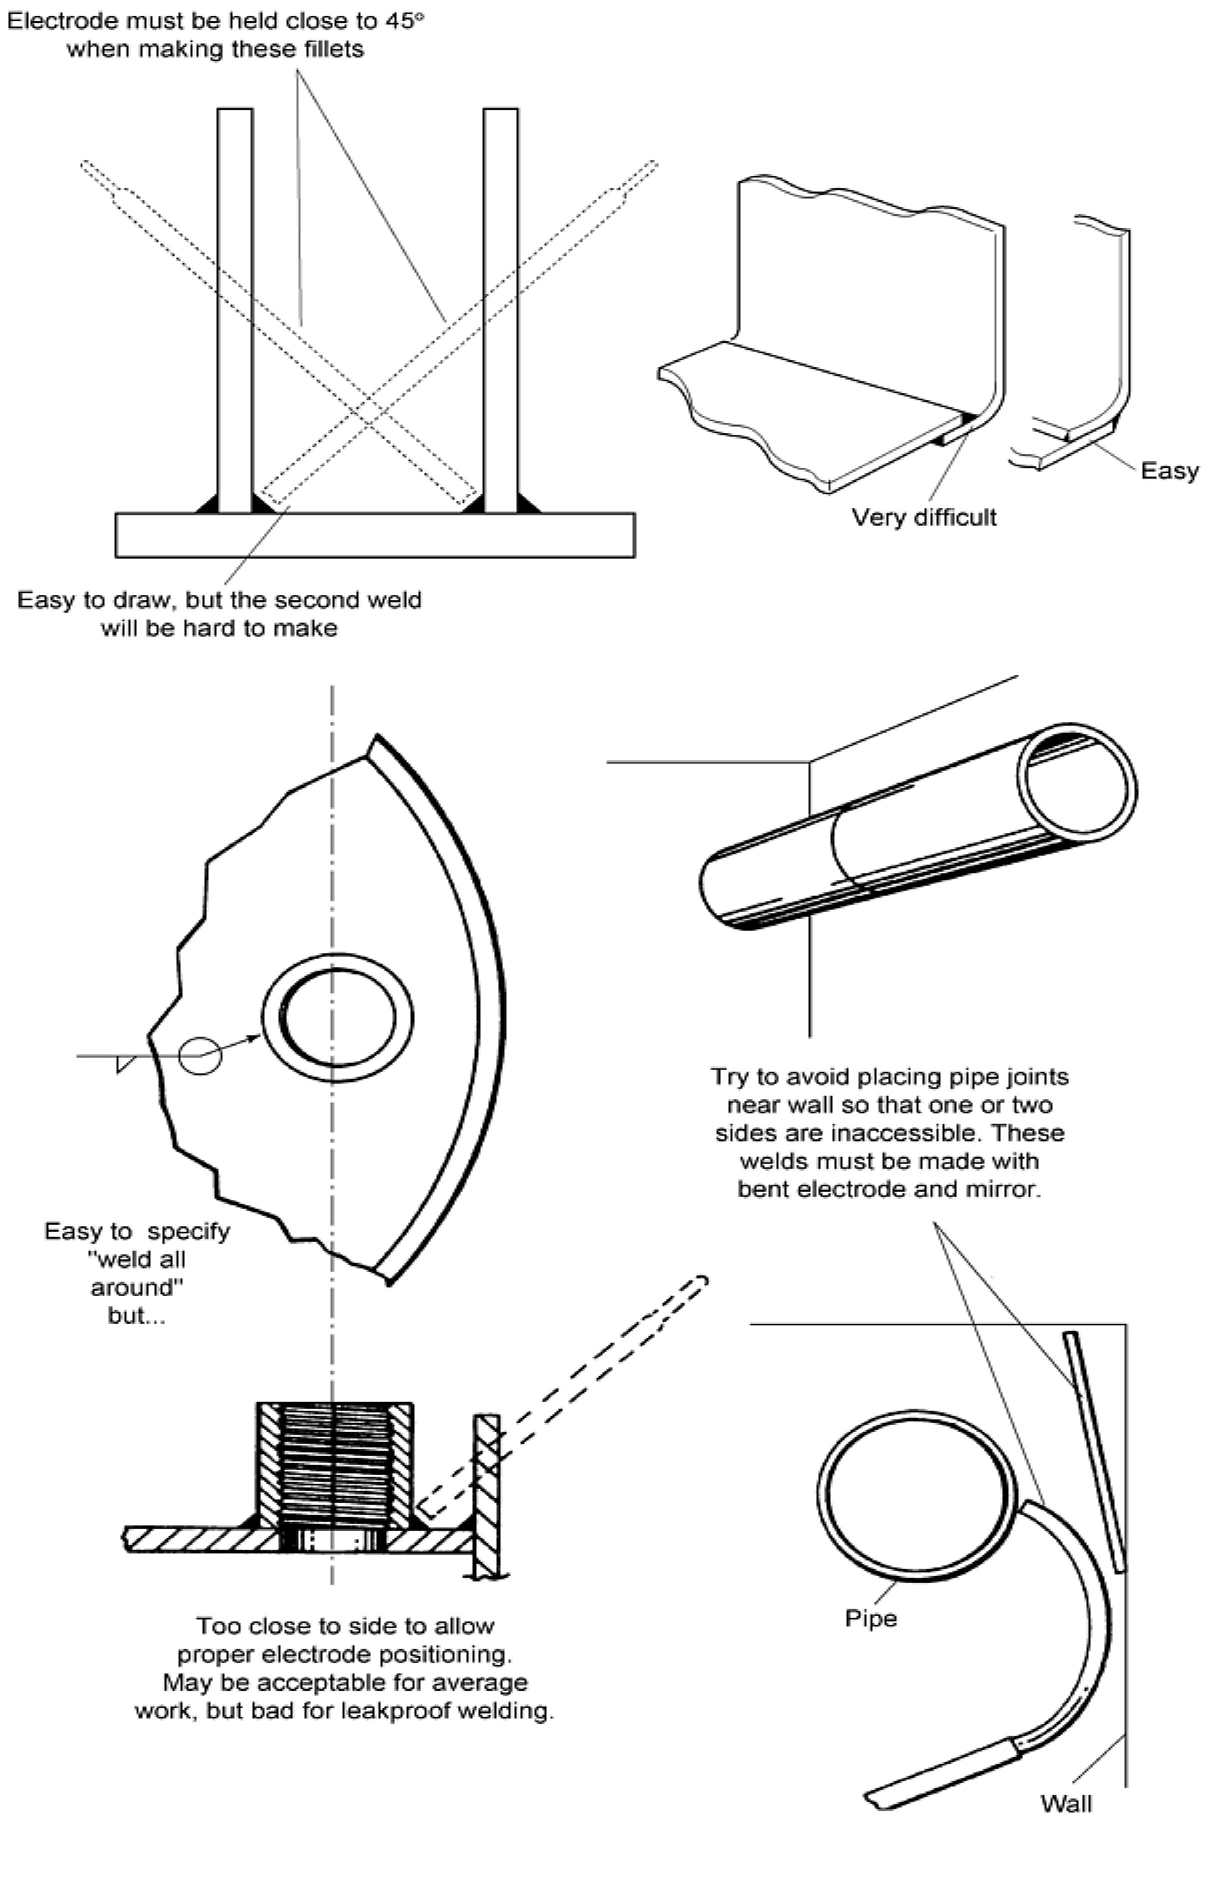

Fig. 5 Effect of joint location on accessibility. Source: Ref 1

Weld joint designs employ bevel angles and root openings to enhance accessibility to the welding torch (or electrode) and provide adequate weld penetration. The best bevel angles provide adequate accessibility while reducing the amount of weld metal required to complete the joint. Currently, computer-based software tools are available to facilitate the selection of a weld joint for minimizing the amount of weld metal. Use of such computer-based selection of joint designs increases welding productivity (joint completion rate), improves quality, and reduces overall fabrication cost, but such designs must be used only when they are consistent with structural design requirements. For this reason, codes such as the ASME Boiler and Pressure Vessel Code, Section IX: Welding Qualifications, and ANSI/AWS D1.1 Structural Welding Code provide flexibility to a welding manufacturer (fabricator) to select or change weld joint design for fabrication, but they require the manufacturer to qualify the welding procedure to meet design performance requirements whenever changes are made to a previously qualified, nonstandard weld joint design. In recent years, the use of narrow-gap gas-metal arc welding and submerged arc welding techniques in the place of conventional welding techniques for welding thick-section pressure vessel steels has contributed significantly to increased weld joint completion rates

Unequal Section Thickness. When constituent members of an assembly exhibit unequal section thicknesses, modifications to the recommended joint designs will be necessary for a variety of technical reasons (Ref 9), but mainly to provide a smooth flow of stress patterns through the unequal sections. When making a fillet weld using an arc welding process, if thicknesses of the members are not greatly different, directing the arc toward the thicker member may produce acceptable penetration. However, special designs for joining will be required when the components to be welded exhibit a large heat sink differential (difference in heat-dissipating capacities). When a thick member is joined to a thin member, the welding heat input (mainly current) needed to obtain a good penetration into the thick member is sometimes too much for the thin member and results in undercutting of the thin member and a poor weld. Similarly, if the proper amount of current for the thin member is used, the heat is insufficient to provide adequate fusion in the thick member, and again a poor weld results. Too little heat input can also cause underbead cracking in certain structural materials.

A widely applicable method of minimizing heat sink differential is to place a copper backing block (Fig. 6) against the thin member during fusion welding (Ref 9). The block serves as a chill, or heat sink, for the thin member. The block can be beveled along one edge so that it can be used when horizontal fillet welds are deposited on both sides of a thin member. Copper backing bars or strips are made in a variety of shapes and sizes to dissipate heat as needed. Often some experimentation and proof testing are required to obtain the optimum backing location and design. Another way to obtain equalized heating and smooth transfer of stress where unequal section thicknesses are being welded is to taper one or both members to obtain an equal width or thickness at the joint. Commonly, when two pipes of dissimilar internal diameter and wall thickness are to be joined, a convenient way is to introduce a "reducer" between the two pipes. One end of the reducer will have the same size and wall thickness as the larger pipe, while the other end of the reducer will have the same size and wall thickness as the smaller pipe.

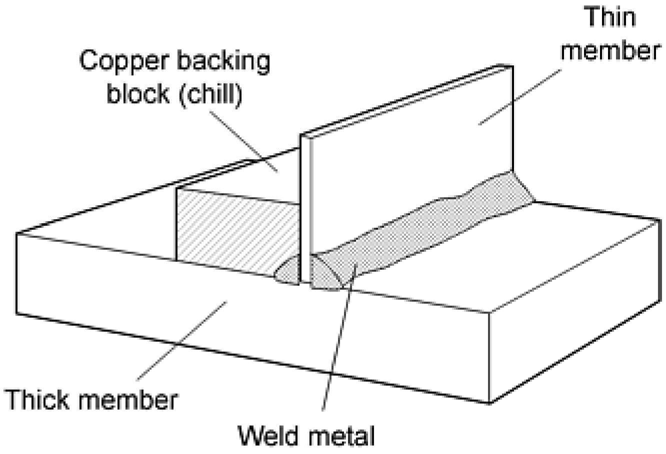

Fig. 6 Use of copper backing bar as a chill to minimize heat sink differential. Source: Ref 9

Distortion Control. Design of an appropriate weld joint can also help reduce welding-related distortion. Fusion welding processes employ localized melting and solidification to join component parts, which can result in excessive thermal strains. These thermal strains are dependent on the type of material, the welding process, and the welding procedure. Thermal strains produced by fusion welding processes can cause residual stresses and distortion, leading to

transverse and angular shrinkage. Reducing the overall length of the weld or the amount of weld metal that needs to be deposited to complete a joint reduces both residual stresses and distortion. For example, intermittent welding instead of continuous welding reduces the overall length of a weld. Similarly, the use of a double-V groove instead of a single-V groove results in the reduction of the amount of weld metal and minimizes transverse shrinkage (Ref 10). Further, the amount of angular shrinkage is strongly influenced by the ratio of the weld metal in the top and the bottom sides of the plate. To minimize the out-of-plane distortion in fillet welded joints, efforts should be directed to using the minimum size of the welds that is consistent with strength considerations.

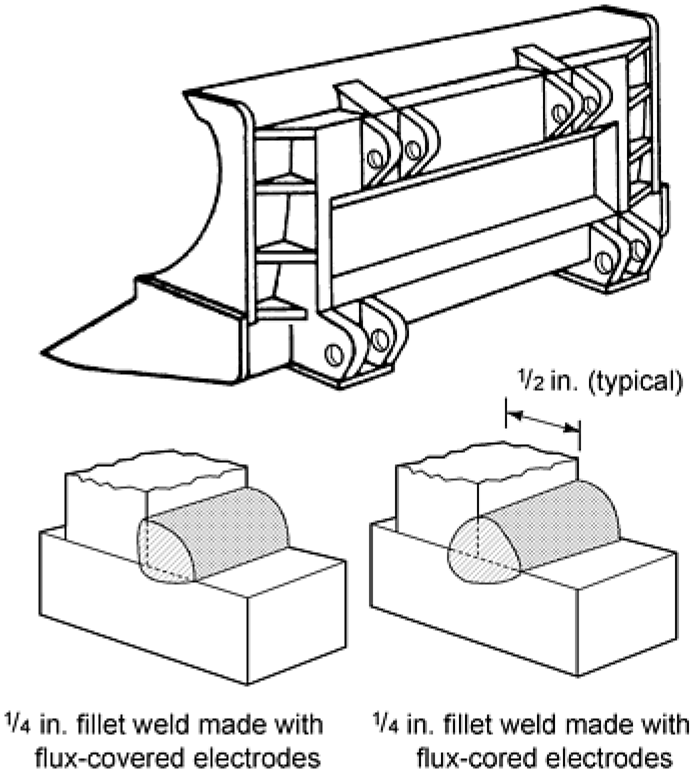
Case Histories

The case histories in this section illustrate the selection of design for joining, based on one or more of the good design practices discussed above. The case histories were compiled from *Welding, Brazing, and Soldering,* Volume 6 of the 9th Edition of *Metals Handbook.* The examples highlight the application of industrial engineering principles to design practices pertaining to fusion welding, diffusion welding, and brazing as they are widely used in the manufacture of components. The basic principles of these design practices are also applicable to other methods of joining such as mechanical fastening, adhesive bonding, soldering, and so on.

Example 1: Process Selection Obviates the Need for Joint Preparation.

Bulldozer blades (Ref 11) were assembled from several low-carbon steel components that had relatively thick sections, generally 13 mm ($\frac{1}{2}$ in.) or more (Fig. 7). Most welds were 6.4 to 13 mm ($\frac{1}{4}$ to $\frac{1}{2}$ in.) fillet welds. A few were groove welds.



Auxiliary gas shielded FCAW	
Joint type	Corner
Weld type	Fillet; some groove
Weld size	6.35 to 12.7 mm ($\frac{1}{4}$ to $\frac{1}{2}$ in.)
Welding position	Flat; horizontal
Number of passes for fillet welds:	
For 6.35 to 7.94 mm ($\frac{1}{4}$ and $\frac{5}{16}$ in.), flat position	1
For 2.03 mm ($\frac{3}{8}$ in.), horizontal position	2
For 0.44 and 12.7 mm ($\frac{7}{16}$ and $\frac{1}{2}$ in.), flat position	1
For 0.44 and 12.7 mm ($\frac{7}{16}$ and $\frac{1}{2}$ in.), horizontal position	3
Shielding gas	Carbon dioxide at 1 m^3/h (35 ft^3/h)
Electrode	2.4 mm ($\frac{3}{32}$ in.) diam flux cored wire
Current	450 A
Voltage	30-32 V
Electrode feed	494 cm (206 in.) per min

Fig. 7 Bulldozer blade and comparison of joint penetration (and actual throat depth) of fillet welds made by shielded metal arc welding and by auxiliary gas shielded flux cored arc welding (FCAW). Low-carbon base metal; low-carbon steel filler metal. Source: Ref 11

To produce fillet welds involving thicker plates, flux cored arc welding (FCAW) was selected in preference to shielded metal arc welding (SMAW), for three reasons: deeper joint penetration, permitting the use of smaller fillets without decreasing the strength of the joint; higher deposition rate; and greater visibility of the arc to the welder, resulting in a better weld. The difference in joint penetration for the two processes is shown in Fig. 7. Use of SMAW to achieve the same level of penetration as FCAW would have required beveling the edge of the vertical member, or an additional number of weld passes. Details for FCAW are given in the table accompanying Fig. 7.

Example 2: Two-Tier Welding.

Electron beam welding provided a unique solution to the problem of designing and fabricating a component of an aircraft gas turbine engine (Ref 12). As indicated in Fig. 8, the component consisted of a cylinder with an external flange on one end, an internal flange on the other, and a tubular annulus between. The components were assembled by welding the trough shape ends of the two subcomponent cylinders by a single two-tier circumferential weld.

Fig. 8 Tiered welds made simultaneously using the electron beam welding process. Source: Ref 12

The components were made of René 41, for service at elevated temperature. The chief welding objectives were to obtain sound welds and to avoid distortion of the part, especially the alignment of the 288 holes located in the annulus less than 13 mm ($\frac{1}{2}$ in.) from the joints. The holes had to be drilled before welding because they could not be deburred if drilled after welding.

Arc welding was rejected as a joining method because it would have been necessary to use internal chills with gas backing in the annulus to minimize distortion and avoid atmospheric contamination. Electron beam welding not only met the basic requirements but also made both joints simultaneously, even though the two joints were separated by approximately 13 mm ($\frac{1}{2}$ in.), as shown in detail A of Fig. 8.

Fixturing was relatively simple. The joints were accurately machined square and the components were assembled between two aluminum plates fitted over the flanges. The plates were connected and forced together by bolts located inside the inner flange. This fixture was then mounted on the faceplate of a welding positioner in the vacuum chamber so that the part would rotate with its axis horizontal. The electron beam gun was in a fixed, overhead position.

Success of the two-tier welding operation depended on careful control of part alignment, beam alignment, beam focal point, power adjustment, and travel speed. The joints for the upper-tier and the lower-tier welds had to rotate in the same vertical plane, although by direct viewing they could not be observed simultaneously. In addition, beam impingement on the joint of the lower-tier weld could be verified only by emergence of the weld bead from the underside, or by sectioning of the test pieces.

Alignment of the part for true horizontal-axis rotation was done with the aid of a precision level (sensitivity of 0.0004 mm per centimeter, or 0.0005 in. per foot) and precision spacer blocks placed on the face of the flange (62 cm, or 24.5 in. OD). Beam alignment was done by centering the beam spot on the reticle of the scope and moving the joint to this position. Beam focal point, beam power, and travel speed were adjusted by trial and error on test components until a satisfactory welding procedure was established. The final settings are shown in the table with Fig. 8. By adjusting the beam focus for an indicated setting midway between the two tiers, the weld shapes of Fig. 8, details B and C, were obtained.

The mushroom-head shape of the upper-tier weld was caused by the defocused condition of the beam at that point, while the somewhat oversize root reinforcement resulted from the excess of power needed to penetrate to and through the lower tier. The relatively narrow face of the lower-tier weld, as well as the narrowing of the weld in its progress through the joints, was explained as an effect of a charged plasma that surrounded and refocused the beam on its passage through the material. The plasma, having a net negative charge, repelled the beam electrons, causing the beam to constrict and to change its focal point. The net result on the lower tier was to produce a weld closely approaching the contour of a normal

single-thickness weld made with a tight, surface-focused beam. Thus, the indicated focal-point setting was more virtual than real.

Both welds were satisfactory as to soundness and shape. Because of lack of access to the interior of the joint, weld spatter and undercutting were of concern, and the spatter associated with penetration of the upper tier was a problem. Most of the particles were loosened with pipe cleaners and were flushed out with solvent at high pressure. The few small particles that remained were judged to be acceptable after radiographic examination. Undercutting was not a problem. The René 41 material was capable of withstanding considerable excess beam power, which was especially important in making the upper-tier weld.

Components produced using the two-tier welding procedure met all test requirements.

Example 3: Design for Diffusion Bonding.

Design for diffusion bonding must facilitate intimate contact of parts and local (microscopic) plastic deformation to promote the formation of a joint. The following example illustrates the use of an innovative joint design that exploits the differences in thermal expansion between parts and tooling (the tooling material exhibits a higher strength than the part material at the bonding temperature) to promote intimate contact, incrementally increase pressure at the joint interface, cause localized plastic deformation, and thereby produce a diffusion bond.

Figure 9 shows diffusion bonding of a titanium part using tooling blocks and spacers of 22-4-9 stainless steel (Ref 13). Initially, the parts and the tooling are fitted into a welded retort made of 1.6 mm (0.063 gage) muffler steel and conforming to the shape of the part. The retort contains an end rail of 22-4-9 spanning the entire width. This end rail contains machined grooves that allow the air to escape when a vacuum pump is turned on. Similar 7.6 cm (3 in.) thick, 22-4-9 plates line the bottom, walls, and opposite end of the retort, and one covers the filled retort before a lid is welded to the retort to seal the container and make it leakproof. To prevent sticking to titanium, all 22-4-9 tooling is surface oxidized by oven baking at 760 °C (1400 °F) for 4 h. During the loading of the retort, titanium slip shims are inserted to separate the tooling blocks slightly from the titanium parts. Later, these shims are removed to create a vacuum path for the air to escape during evacuation of the retort. A steel tube is used to connect the retort with a vacuum pump.

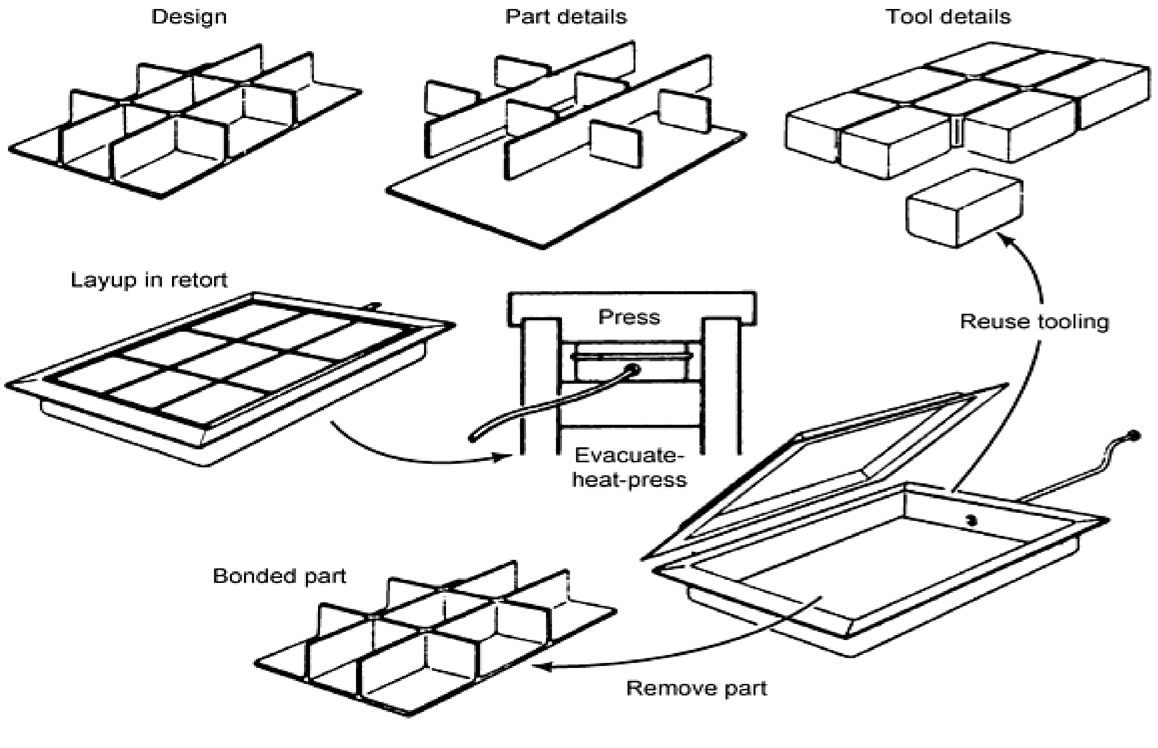

Fig. 9 Processing sequence during diffusion bonding of a titanium part using stainless steel tooling. Source: Ref 13

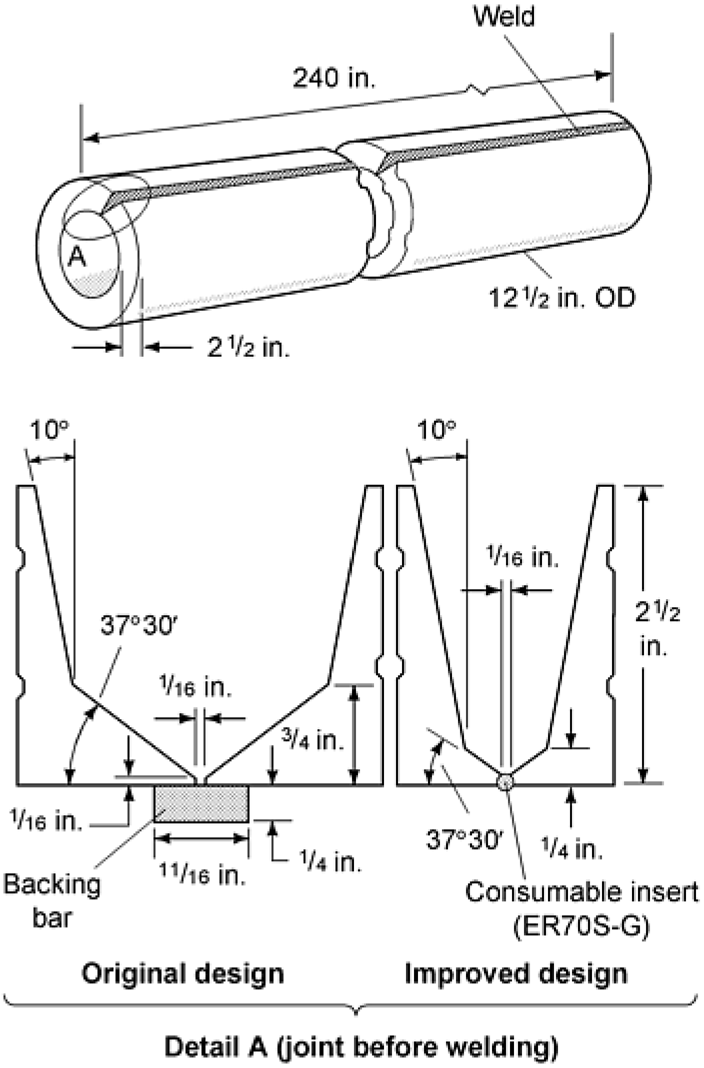
Initially, the container is evacuated to 0.13 Pa (10^{-3} torr) vacuum and checked for leaks. A higher vacuum, below 1.3×10^{-4} Pa (10^{-6} torr), is then obtained. The leakproof container is placed within reusable ceramic blocks, which in turn are covered by steel plates containing thermocouples. The entire assembly is placed in a bonding press. The ceramic blocks that press against the top and bottom of the retort contain heating coils that bring the entire assembly to about 927 °C (1700 °F). The ceramic blocks on the sides and ends of the retort transmit heat and pressure to the assembly during bonding. A press is used to apply about 13.8 MPa (2000 psi) pressure on the retort in all directions, and the retort is held at the bonding temperature and pressure for about 2 to 12 h. Thermal expansion of the titanium part against the relatively rigid stainless steel tooling allows intimate contact of the titanium parts across the joint line, and it facilitates localized plastic deformation and the formation of a diffusion bond. Following the bonding cycle, the entire assembly is cooled slowly and dismantled, and then the retort is cut open to retrieve the diffusion-bonded titanium part. Generally, the tooling is reused, while the retort (made from cheap muffler steel) is scrapped.

Example 4: Revision of Joint Design to Reduce Cost.

The longitudinal butt joints in 6.1 m (20 ft) long sections of SA-106, grade B carbon steel pipe (Ref 14) used for power-boiler headers were originally designed as shown at lower left in Fig. 10. With this design, the root pass and the second pass were made by SMAW using a backing bar, and then the weld was completed by submerged arc welding (SAW).



Welding conditions for improved design	
Welding process:	
Root pass	GTAW
Second pass	SMAW

Remainder	SAW
Power supply	
GTAW, SMAW	200 A transformer-rectifier[a]
SAW	600 A motor-generator[b]
Edge preparation	Machined
Preheat	121 °C (250 °F) min
Filler metal (low-carbon steel)	
GTAW (argon shielding)	ER70S-G consumable insert
SMAW	E7018
SAW	EL12
Power setting:	
GTAW	90 A (DCEN); 12 V
SMAW	121 A (DCEP); 23 V
SAW	450 A (DCEP); 30 V
Interpass temperature	260 °C (500 °F) max
Postheat	Stress relieve at 621±25 °C (1150±25 °F)[c]

With the original joint design, the root and second passes were made by SMAW using a backing bar. Weld was then completed by SAW. With the improved joint design, the root pass was made by GTAW using a consumable insert (no backing), the second pass by SMAW, and the remainder by SAW.

(a) With high-frequency start, and slope control.

(b) Weld head on boom-type manipulator, workpiece supported on power and idler rolls for turning.

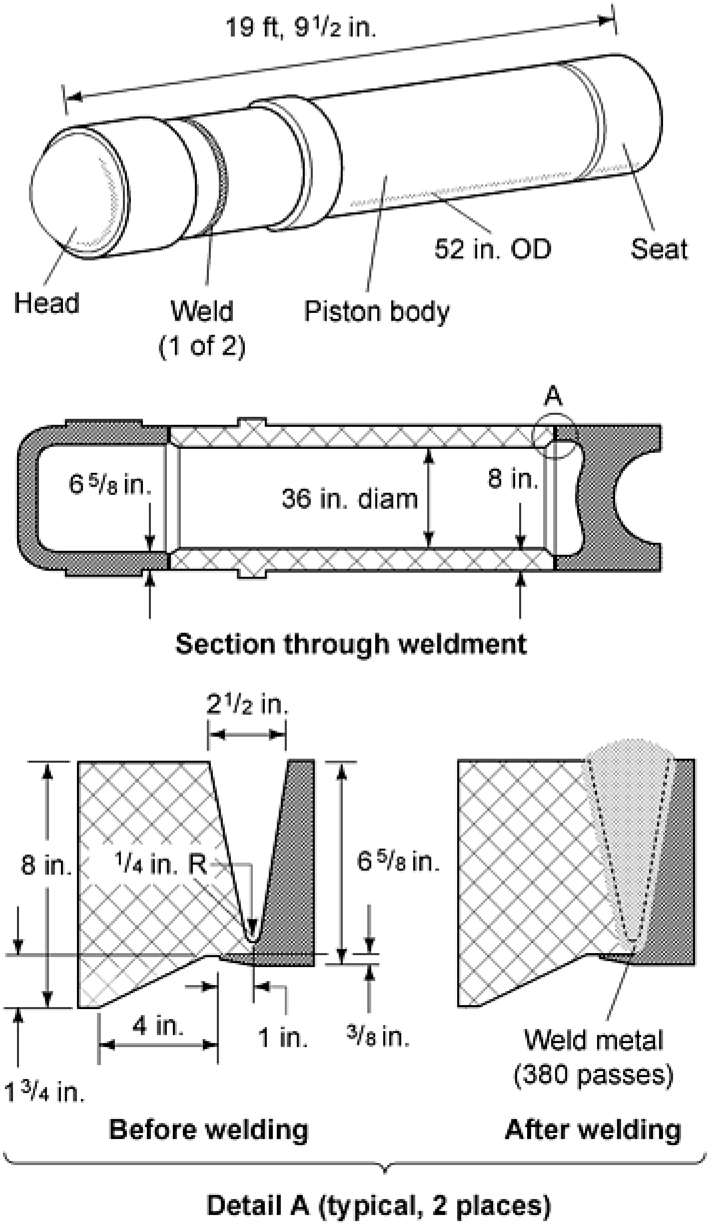
(c) In furnace. 1 h per 25 mm (1 in.) of section

Fig. 10 Revision of joint design. Use of a consumable insert permitted change to a lower-cost method of welding boiler-header pipes. Carbon steel (SA-106, grade B; 0.30 max C) base metal; low-carbon steel filler metal. GTAW, gas-tungsten arc welding; SMAW, shielded metal arc welding; SAW, submerged arc welding. Source: Ref 14

To reduce the cost, the joint design was revised to that shown at lower right in Fig. 10. This permitted making the root pass by gas-tungsten arc welding (GTAW), using a consumable insert, instead of by SMAW with a backing bar. Then, as with the original joint design, the second pass was made by SMAW, and the weld was completed by SAW. The SMAW process was used for the second pass to provide a deposit thick enough to ensure against melt-through by SAW. The improved joint design and change in welding procedure resulted in a 25% saving in cost (material, labor, and overhead) per foot of seam welded.

Example 5: Submerged Arc Welding of a Large Piston.

The large hydraulic-jack piston shown in Fig. 11 was assembled by welding three low-carbon steel castings (head, piston body, and seat) at girth joints (Ref 15). When similar smaller pistons with wall thicknesses of 7.6 to 12.7 cm (3 to 5 in.) had been assembled by SMAW, about one welded joint in eight was found to be defective and had to be reworked.



Conditions for SAW	
Joint type	Circumferential butt
Weld type	Single-U-groove, integral backing
Joint preparation	Machining
Power supply	1000 A transformer
Wire feed	Fully automatic, constant speed
Welding head	Machine held, air cooled
Fixture	50 ton variable-speed roll
Auxiliary equipment	Exhaust fan, vacuum flux remover, positioning arm
Electrode wire	2.4 mm ($\frac{5}{32}$ in.) diam EL12[(a)]
Flux	F71[(a)]
Welding position	Flat (horizontal-rolled pipe position)
Number of passes	380
Current and voltage:	
Passes 1 through 3	700 A, ac; 38 V
Remaining passes	750 A, ac; 40 V
Preheat	204 °C (400 °F) (by torch)
Postheat (stress relief)	7 h at 600 °C (1115 °F), furnace cool to 315 °C (600 °F)

Welding speed	24 cm (9 $\frac{1}{2}$ in.) per min

(a) Electrode and flux yielded a weld deposit containing 0.12 C, 0.84 Mn, 0.72 Si, 0.018 S

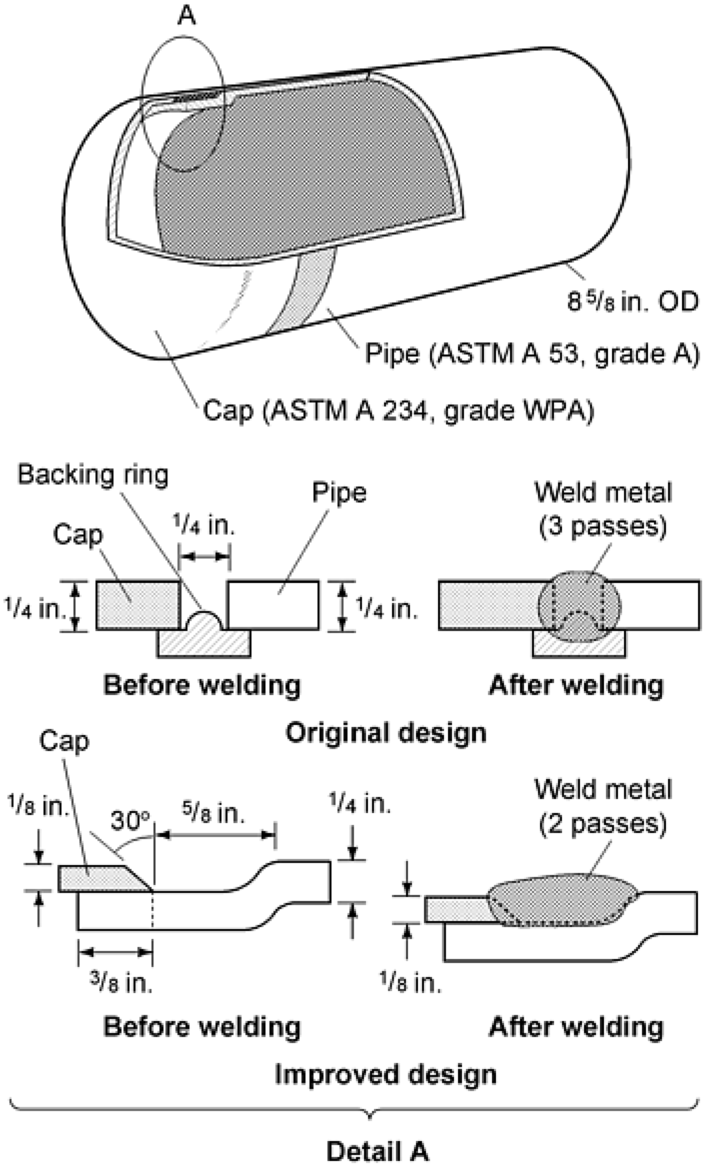
Fig. 11 Large piston assembled by submerged arc welding (SAW). Low-carbon steel base metal; low-carbon steel filler metal (EL12). Source: Ref 15

Because of the experience with the pistons with 7.6 to 12.7 cm (3 to 5 in.) wall, it was decided to use SAW to assemble four large pistons, in which a 19.2 cm (8 in.) wall was to be joined to a 16.8 cm (6 $\frac{5}{8}$ in.) wall, using the joint design shown in detail A. The outside surfaces of the three castings to be welded were rough machined and the joints were prepared by machining. The joints were of the interlocking type (see Fig. 11, detail A) and provided support for the unwelded components during positioning on variable-speed welding rolls. Joint areas were preheated to 204 °C (400 °F) with the gas torches as the piston was rotated. The welds were made in 380 passes and were produced oversize and machined to size after magnetic-particle inspection and stress-relief. The welded pistons were stress relieved at 600 °C (1115 °F) for 7 h and furnace cooled to 315 °C (600 °F).

Each welded joint was ultrasonically inspected for a distance of 7.6 cm (3 in.) on each side of the weld. After inspection, the pistons were hydrostatically tested at 2 MPa (300 psi). There were no rejections. Production time for welding the large piston was 101 h, which was a considerable improvement over the production time of 212 h for the smaller pistons assembled by SMAW.

Example 6: Use of an Offset to Eliminate Backing Rings.

A component of a heat-exchanger shell assembly (Ref 15) was initially made by SAW: a medium-carbon steel pipe cap with a wall thickness of 6.4 mm ($\frac{1}{4}$ in.) was attached to a low-carbon steel pipe of the same wall thickness by means of a circumferential butt joint, supported and aligned by a backing ring, as shown in the "original design" in Fig. 12.



Joint type	**Joggled lap**
Weld type, original design	Square-groove, with backing ring
Weld type, improved design	Modified single-V-groove, with integral backing
Joint preparation:	
Original design	Backing ring machined
Improved design	Cap end machined, pipe end reduced
Electrode wire	3.2 mm ($\frac{1}{8}$ in.) diam EL12
Flux	F62
Welding position	Flat (horizontal-rolled pipe)
Welding voltage	25 to 26 V
Welding current	350 to 410 A (DCEN)
Welding speed	46 to 51 mm (18 to 20 in.) per min
Number of passes, original design	Three
Number of passes, improved design	Two
Power supply	40 V, 600 A transformer-rectifier (constant-voltage)
Fixturing	Chuck-type turning rolls; alignment clamps for tack welding

Fig. 12 Cap-to-pipe weldment. Low-carbon steel welded to medium-carbon steel; low-carbon steel filler metal

(EL12). Source: Ref 15

When it became apparent that the wall thickness of the pipe cap could be less than that of the pipe without adversely affecting service performance, the joint was rede-signed as a joggled lap joint (see "improved design," Fig. 12). The offset incorporated in the pipe for the redesigned joint took the place of the backing ring previously used and furnished a locating surface for the cap. The redesigned joint was made by SAW under the same conditions as those for the original joint, except that only two passes were required, rather than three.

Cost reduction was realized from eliminating the backing ring, from the savings in material resulting from the use of thinner pipe caps, and from eliminating one circumferential welding pass. The change in joint design led to a savings of approximately 35% in total factory cost. All joints were inspected visually and radiographically to check for full penetration and absence of slag inclusions. The rejection rate was less than 1%.

Example 7: Elimination of Backing Bars.

A 3.7 m (12 ft) long header assembly for a large high-pressure heat exchanger (Ref 15) was manufactured to Section VIII, Division I, of the ASME Boiler and Pressure Vessel Code (Fig. 13).

	Original design	Improved design
Welding process	Manual FCAW	Automatic SAW

Electrode	2.4 mm ($\frac{3}{32}$ in.) diam flux cored wire	2.4 mm ($\frac{3}{32}$ in.) diam solid wire
Flux	. . .	F72
Welding position	Flat	Flat
Root-pass welding conditions		
Welding current[(a)], A	375-425	460-480
Number of passes per joint	1	1
Welding speed, cm/min (in./min)	15 (6)	20 (8)
Filler-pass welding conditions		
Welding current[(a)], A	375-425	400-600
Deposition rate, kg/h (lb/h)	2.7 (6)	8.2 (18)
Number of passes per joint	7-8	5
Welding speed, cm/min (in./min)	25 (10)	56 (22)[(b)]

(a) Power supply for welding of both designs was an 80 V (open-circuit) transformer-rectifier.

(b) Welding speed for the first filler pass was 71 cm/min (28 in./min).

Fig. 13 Submerged arc welding (SAW) setup for heat-exchanger header. Carbon steel, 0.35% max C (ASTM A 515, grade 70) base metal; carbon steel filler metals. FCAW, flux cored arc welding. Source: Ref 15

As originally designed (see upper left in Fig. 13), for manual FCAW from the outside, the assembly consisted of four steel components and was welded at corner joints that incorporated backing bars, as shown in Fig. 13, section A-A. It was difficult to ensure a uniformly tight fit of the backing in the joint. Under radiographic inspection, slag was revealed that ran between the backing bars and the adjacent 38 mm (1$\frac{1}{2}$ in.) thick components.

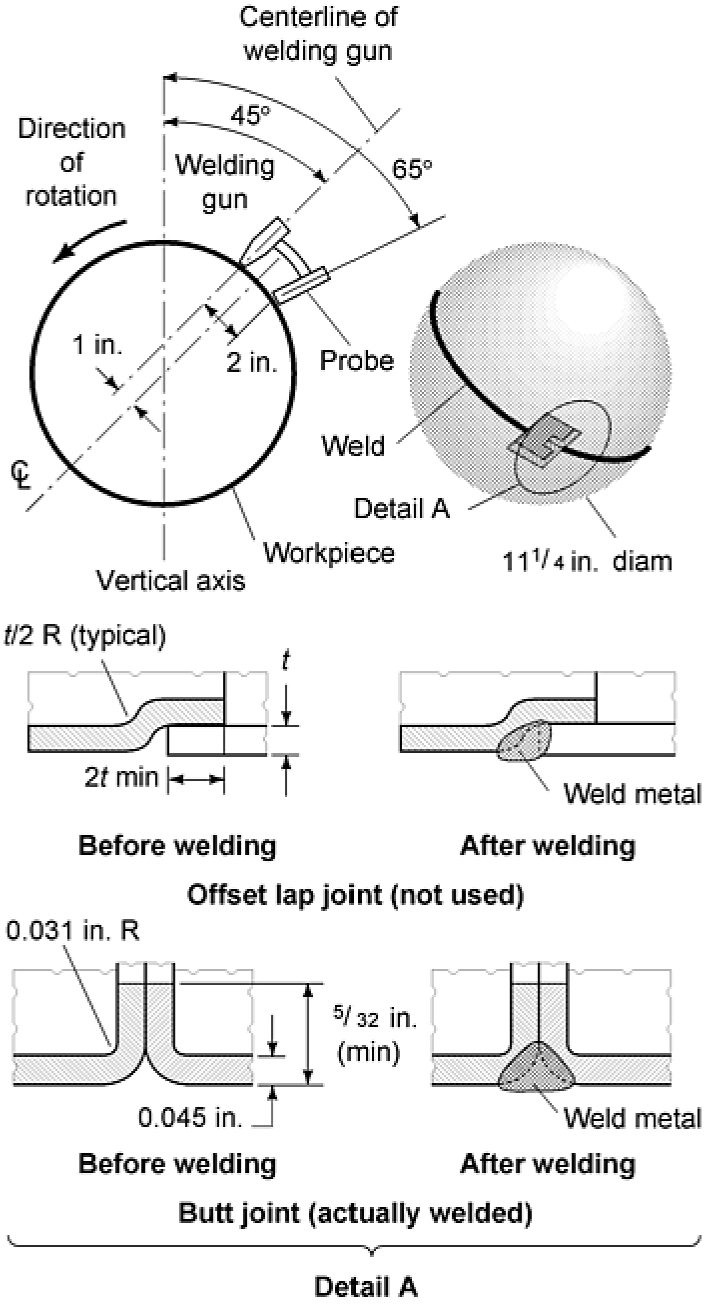
The problem was eliminated by redesigning the header assembly for automatic SAW without backing bars. The redesigned assembly, shown in the upper right of Fig. 13, consisted of two 38 mm (1$\frac{1}{2}$ in.) thick channels formed in a press brake. The two components were welded at two longitudinal butt joints of the double-V-groove design (Fig. 13, section B-B).

For this improved design, the welding was done by the use of a boom-mounted automatic welding head. The formed channels were held stationary while the welding head was advanced along the joints. First, root passes were made along the inside grooves of the two joints, then filler passes were made along the outside grooves. After the root passes, the outside grooves were machined-out to sound metal before the filler passes were begun.

A major benefit of the change to two-piece design was that only about one-third as many filler passes were required for the entire weldment (10 passes, as compared with 28 to 32 passes for the original four-piece design).

Example 8: Use of Modified Butt Joint to Save Tooling and Labor Costs.

An offset lap joint (middle view in Fig. 14) is frequently used in welding the components of a variety of pressure cylinders and spheres. However, the use of this lap joint for welding the spherical refrigerant container shown in Fig. 14 would have resulted in high labor and tooling costs. The lip of the offset hemisphere would have caused interference in assembly, and additional tooling would have been needed to offset the lip.



Joint type	Circumferential modified butt
Weld type	Single-flare V-groove
Power supply	300-A transformer-rectifier
Electrode wire[(a)]	0.162 mm (0.030 in.) diam ER70S-3
Welding gun	Mechanized, fixed, water cooled
Wire feed	Push-type motor, on welding gun
Current	170-190 A (DCEP)
Voltage	22-23 V
Shielding gas[(b)]	98% argon-2% oxygen, 1 m^3/h (35 ft^3/h)
Number of passes	1
Wire-feed rate	863 to 965 cm (340-380 in.) per min
Electrode extension	6.35 to 9.5 mm ($\frac{1}{4}$ - $\frac{3}{8}$ in.)
Welding speed	118 cm (46.6 in.) per min
Weld time per container	42 s

(a) Selection of wire wound to a large diameter

	eliminated need for wire straighteners and reduced leakage rate.
(b)	Argon of 99.999% purity from bulk-liquid holder

Fig. 14 Girth welded refrigerant container. Labor and tooling costs were reduced by use of a modified butt joint instead of an offset lap joint. Low-carbon steel (ASTM A 620) 0.045 in. base metal; low-carbon steel filler metal (ER70S-3). Source: Ref 16

The modified butt joint shown at the bottom in Fig. 14 allowed use of identical forming tools for both halves of the sphere and was the best compromise among weldability, tooling costs, and labor costs (Ref 16). To reduce labor costs still further, each welder operated two girth welding machines and thus was not able to observe the welding operation; therefore, automatic seam tracking was necessary.

The automatic seam tracking system consisted of two recirculating ball-screw cross-slides mounted at right angles and driven by reversible alternating current motors. A probe, which was mounted to move with the welding gun (see view at upper left in Fig. 14), sensed the location of the joint in relation to the gun. A movement of the probe tip caused the appropriate slide to bring the probe and gun back to the neutral position. The probe was mounted on a small screw-adjusted slide to provide quick and accurate adjustment of both the horizontal position of the welding gun and the distance between it and the work. At the end of the welding cycle, the probe and the welding gun were raised by the vertical slide. After the next assembly was in place, the probe and gun were lowered by the same means and welding was started automatically.

The hemispheres were held in a special welding machine (lathe) consisting of one fixture rotated by a continuously variable drive and a second fixture mounted on the tailstock. Both fixtures were mounted on air-operated slides. Thus, the parts were held together and rotated under the welding gun. When the gun was retracted after completing the weld, the air cylinders separated, releasing the welded workpiece.

The operator loaded the hemispheres in the machine and pushed a button to close the fixtures. The operator then had an option of using automatic start, whereby the weld started as soon as the welding gun was in position, or manual start, whereby the position of the gun could be observed, corrections could be made (if required), and the weld could be started by pushing a button. While one container was being welded, the operator loaded and started a second machine. After each container had been welded, the operator checked it for visible defects. The containers requiring repair welding were set aside, and those with no visible defects were transferred on a conveyor to a testing area.

The workpiece was a disposable refrigerant container with a water capacity of 11.6 kg (25.5 lb), produced under a special permit that specified two types of pressure tests. Each welded container was tested by subjecting it to 2.1 MPa (300 psi) internal air pressure while within a heavy steel safety chamber. The pressure in the container was then reduced to 0.7 MPa (100 psi), the chamber was opened, and the sphere was forced under water to check for leaks. If repairs were required, the spheres were resettled after repair. A destructive test was required on one container out of each lot of 1000, with a minimum of one per day (although, in practice, at least one container was tested from each machine during each shift). This test consisted of filling the container with water, connecting it to a high-pressure pump, and increasing the pressure until the container burst. The minimum bursting strength was 5.5 MPa (800 psi). Fewer than 5% of the spheres required weld repairs.

The guidance system caused some problems, primarily because of the maintenance required. Repair and adjustment of the probe switch were difficult, and improperly adjusted probes sometimes caused misplaced welds. Spare systems were available for replacement of defective probe units.

Although the guidance system added to the machine cost and caused maintenance problems, these disadvantages were soon canceled out by decreased welding costs. Satisfactory welds were difficult to produce manually, because the horizontal variance of the welding gun position had to be held to 0.8 mm ($\frac{1}{32}$ in.) to prevent melt-through. In addition, it would have been necessary for the manual operator to correct for differences in the heights of the weld seams, limiting the welder to operating one machine and thus doubling the labor cost.

The hemispheres were press formed and vapor degreased. No edge preparation or postweld finishing was done. Welding conditions are given in the table with Fig. 14.

Example 9: Joining Sections of Unequal Thickness.

An application involving components of unequal section thicknesses (Ref 9) is the welding of heat-exchanger tubes having 2.4 mm (0.093 in.) wall thickness to a tube sheet as thick as 25.4 cm (10 in.). The usual method of avoiding difficulty is to cut a circular groove, 6.4 mm ($\frac{1}{4}$ in.) deep, in the upper surface of the tube (Fig. 15). By restricting heat transfer, this groove minimizes heat sink differential between the thin tube wall and thick tube sheet.

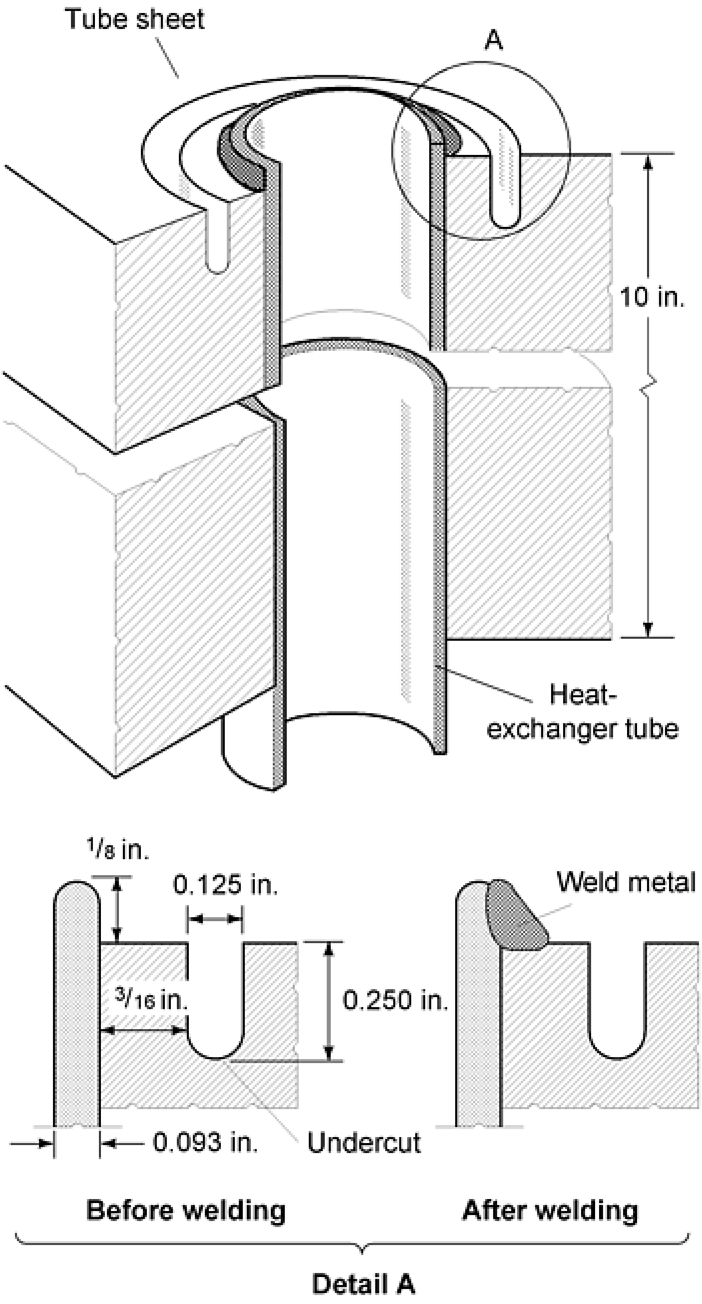


Fig. 15 Thick tube sheet with machined groove. Minimizes heat sink differential during welding of thin-walled heat-exchanger tube to the tube sheet. Low-carbon steel base metal; low-carbon steel filler metal. Source: Ref 9

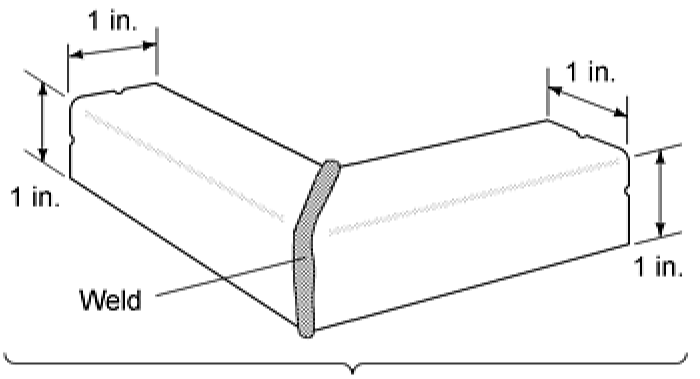
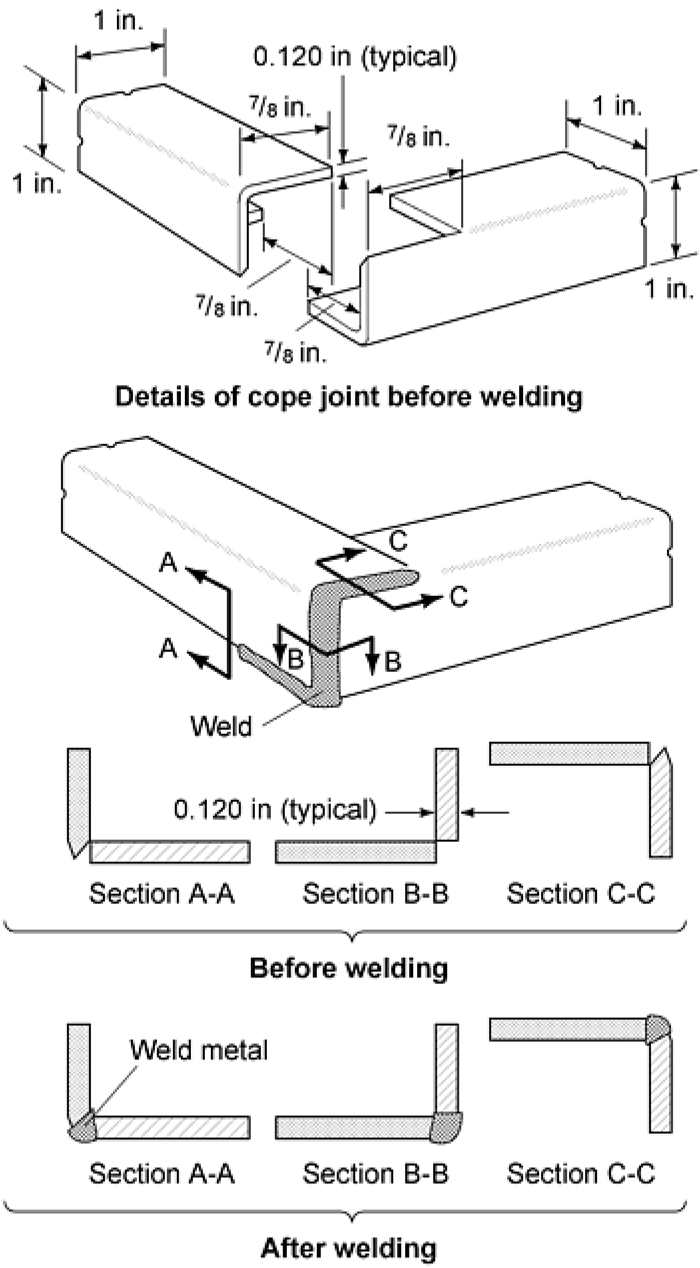
Example 10: Redesign of a Joint to Improve Dimensional Control.

The corner-welded channel sections shown in Fig. 16 were parts of rectangular frames for data-processing machines (Ref 17). Originally, 45° miter joints were used (Fig. 16a), but dimensions after welding were unsatisfactory because of joint location and weld restraint.



(a) Original design (miter joint)



(b) Improved design (cope joint)

Joint type	Corner
Weld type	Fillet and V
Power supply	200 A, constant-voltage rectifier
Electrode wire[(a)]	0.76 mm (0.030 in.) diam ER70S-2
Wire feed	Constant feed
Current	80-85 A (DCEN)
Voltage	26 V
Shielding gas	75% argon-25% carbon dioxide, at 1.1 m^3/h (40 ft^3/h)
Wire-feed rate	76-254 cm (30-100 in.) per min
Welding speed	25 cm (10 in.) per min

(a) 0.04% C; triple deoxidized, with flash copper plating

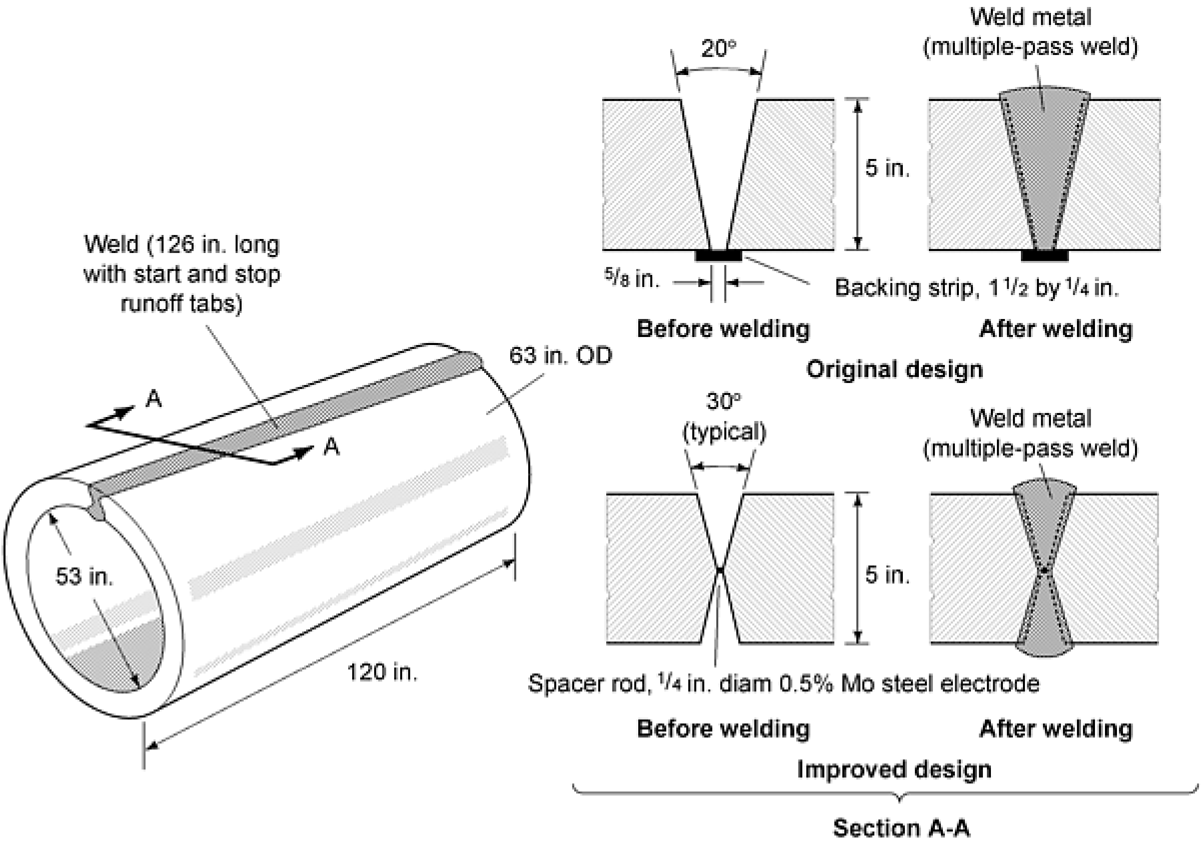
Fig. 16 Corner section of a rectangular frame. A cope joint was substituted for a miter joint to improve dimensional control. Low-carbon steel base metal; low-carbon steel filler metal (ER70S-2). Source: Ref 17

To provide a more positive joint location with less weld restraint, cope joints (Fig. 16b) were substituted for the miter joints. Tolerances of ±0.25 mm (±0.010 in.) on length and width, and ±0.813 mm (±0.032 in.) on squareness, were met on channel sections welded with the improved joint design.

The channel sections were contour roll formed from 3.05 mm (0.120 in.) thick low-carbon steel strip. Pieces were cut to length by a cutoff die in a press. The cut lengths were also coped by a die in a press, and all parts were inspected. Tolerances on individual pieces were held to ±0.127 mm (±0.005 in.).

Example 11: Change in Joint Design to Reduce Distortion and Cost.

Figure 17 shows a 305 cm (120 in.) long steam-drum shell course, roll formed with a welded longitudinal seam (Ref 15). Originally, the butt joint for this seam was of single-V-groove design and was welded with the use of a backing strip (see "original design" in section A-A in Fig. 17). Fit-up and removal of the backing strips were time-consuming operations, and welding from one side distorted the weldment.



Welding conditions for both joint designs	
Weight of electrode and flux deposited per hour	7.1 kg (15.6 lb)
Weight of electrode and flux deposited per foot of weld:	
Original design (single-V-groove)	11.8 kg (26 lb)
Improved design (double-V-groove)	6.4 kg (14 lb)
Deposition efficiency	98%
Length of weld (including runoff tabs at ends)	3.2 m ($10\frac{1}{2}$ ft)
Time for installing and removing backing strip (original design)	12 h
Joint type	Butt
Weld types	Single-V-groove (original); double-V-groove (improved)
Welding position	Flat[a]
Arc starting	Touch and retract
Preheat	79 °C (175 °F), then 121 °C (250 °F) (propane torch)
Interpass temperature	260 °C (500 °F)
Postheat	621±25 °C (1150±25 °F) (furnace), 1 h/25 mm (1 in.) of section
Root passes (SMAW):	
Power supply	300 A motor-generator
Electrode	4.8 mm ($\frac{3}{16}$ in.) E7018
Current and voltage	250 A (DCEP); 24 V
Intermediate passes (single-electrode SAW):	
Power supply	900 A motor-generator
Electrode wire	5.6 mm ($\frac{7}{32}$ in.) diam 0.5% Mo steel[b]
Current and voltage	700 A (DCEP); 30 V
Travel speed	48 cm (20 in.) per min
Final passes (tandem SAW)[c]	
Leading head:	
Power supply	900 A motor-generator
Electrode wire	5.6 mm ($\frac{7}{32}$ in.) diam 0.5% Mo steel[b]
Current and voltage	800 A; 30 V
Trailing head:	
Power supply	1000 A transformer
Electrode wire	2.4 mm ($\frac{5}{32}$ in.) diam 0.5% Mo steel[b]
Current and voltage	700 A, ac; 35 V
Travel speed	76 cm (30 in.) per min

(a) Workpiece supported on one power roll and one idler roll.

(b) Electrode wire contained 0.11% C, 0.50% Mo, 0.85% Mn, and was used at a 1-to-1 ratio of wire to flux.

(c) Tandem welding head was mounted on a boom-type manipulator.

Fig. 17 Submerged arc welding setup for steam-drum shell course. Based metal: carbon steel, 0.35% max C (ASTM A 515, grade 70), normalized. Filler metals: low-carbon steel (E7018) for root passes (shielded metal arc welding); 0.5% Mo steel for remaining passes (submerged arc welding). Source: Ref 15

The joint was changed to a double-V-groove design (shown as "improved design" in section A-A of Fig. 17). This change resulted in the need for much less weld metal; the need for a backing strip was eliminated; and distortion was reduced by sequential deposition of weld beads on the inside and outside of the joint. The amount of back gouging needed was less than that required to remove the backing strip from the single-V-groove weld. As a result of these improvements, electrode, flux, and labor costs were reduced by 46%, and the total cost of welding was reduced by 62%. Welding procedures and post-weld operations for the two designs are described below. For both designs, the shell courses were hot roll formed into a cylinder and descaled, and the joint grooves were flame cut.

Originally, the single-V-groove joint was preheated to 79 °C (175 °F) with a propane torch, the backing strip was installed, and the temperature of the joint was raised to 121 °C (250 °F). At least two root passes were made, using SMAW. This operation was followed by depositing six single-pass layers, each 3.2 mm ($\frac{1}{8}$ in.) thick, by single-electrode SAW. Tandem SAW was used to complete the weld, single-pass layers 3.2 mm ($\frac{1}{8}$ in.) thick being deposited to a weld level of 38 mm ($1\frac{1}{2}$ in.), followed by two-pass (split) layers 3.2 mm ($\frac{1}{8}$ in.) thick. Then the backing strip was removed by air carbon arc gouging and grinding, and back welding was done, as required, to provide a flush joint.

In the improved design, the double-V-groove joint was also preheated in two stages (79 and 121 °C, or 175 and 250 °F) with a propane torch, except that instead of a backing strip being installed between stages, a spacer rod of 6.4 mm ($\frac{1}{4}$ in.) diameter 0.5% Mo steel electrode material was tacked in place and seal welded by SMAW. Shielded metal arc welding was used also for root passes. The first increment of single-electrode submerged arc welds consisted of eight 3.2 mm ($\frac{1}{8}$ in.) thick single-pass welds on the outside of the weldment. The workpiece was rotated 180°, and the joint was back gouged and ground to a radius of 6.4 to 9.5 mm ($\frac{1}{4}$ to $\frac{3}{8}$ in.). The first increment of welding on the inside of the joint consisted of 3.2 mm ($\frac{1}{8}$ in.) thick single-pass welds to a 38 mm ($1\frac{1}{2}$ in.) level, using single-electrode SAW. Then the workpiece was again rotated 180°, and the remainder of the outside welding was completed using tandem SAW to deposit two-pass (split) layers of 3.2 mm ($\frac{1}{8}$ in.) thickness. After a final 180° rotation of the workpiece, the inside welding was completed using the same sequence of two-pass tandem SAW of 3.2 mm ($\frac{1}{8}$ in.) thickness.

Future Directions

The foregoing examples illustrate that value engineering, methods study, and time study principles can be applied to select the best design for joining of parts. Future efforts could be directed toward developing computer-based simulations with graphic user interfaces that would integrate appropriate part design and manufacturing databases. Such efforts would

allow one to effectively consolidate existing knowledge on basic design practices, design criteria for joining, and appropriate case examples involving parts and processes. These computer-based simulations can serve as powerful learning tools, and their effective use can be expected to eliminate or minimize trial-and-error methods of design for joining, and thereby facilitate agile manufacturing at minimal cost.

Design for Heat Treatment

William E. Dowling, Jr. and Nagendra Palle, Ford Motor Company

Introduction

THE SELECTION OF MATERIALS and manufacturing processes for a component design is a complex process and often involves iterative decision making. The component is designed to provide a specific mechanical function, and its design is often limited by space and cost considerations. The component must be able to survive extreme external loading conditions from thermal and/or applied mechanical forces. Therefore, a high level of performance needs to be achieved at a minimum cost. Based on the design and loading conditions, a material and manufacturing process are selected to cost effectively provide adequate properties for the operating environment. Very often a low-cost material and processing combination requires heat treatment after component shaping to enable the part to meet its design criteria. The relationship between performance at minimum cost, design, material, and the manufacturing process is analogous to a three-legged stool with all legs having equal importance. In order for a component to fulfill its cost and performance criteria, its design should accommodate all the loading conditions of the component, its material properties should meet the expectations of the design, and its manufacturing processes should produce the component at a minimum cost.

The mechanical design process has evolved from an experience-based process using design factors, such as stress-concentration factors, and design rules (based on experimental data) to the current reliance on analytical processes. The ability to analytically design components combined with the constant desire for system cost reduction while achieving greater performance has led to decreased design times and increased component complexity. The designer, when provided with accurate component loading information, can accurately assess part life with reliable input of experimentally determined material properties. These material property databases are continually growing, both in the open and in proprietary databases (see the article "Sources of Materials Properties Data and Information" in this Volume). In addition to these databases, the mechanical properties resulting from a broad range of heat treatment processes, for many classes of materials, are well documented. The ability to select materials and process parameters to achieve the desired property goals is becoming more automated as evidenced by the success of Jominy hardness and carburizing prediction programs

(Ref 1). The foundation of the currently used design practices requires a close relationship among analytical design procedures, material property databases, and the ability of the heat treat process to achieve desired mechanical properties.

In addition to providing appropriate physical and mechanical properties to meet design requirements, heat treatment also produces dimensional changes and residual stress patterns that in some cases can lead to component cracking. The dimensional changes and residual stresses produced by heat treatment are very sensitive to geometric and processing specifics. Currently, the relationship between design, dimensional changes, residual stresses, and cracking is determined by experience and results in the development of general rules for design. Prototype component designs must be experimentally evaluated and iterated to bring the component within acceptable tolerances for dimensions and residual stresses. A clear need for reducing development costs has motivated significant corporate and academic research in the area of analytical prediction of the response of a component to heat treatment.

This article presents an overview of techniques that are currently in use to design for heat treatment. The primary design criteria addressed in this article are the minimization of distortion and undesirable residual stresses. The article presents both theoretical and empirical guidelines to understand sources of common heat treat defects and how they can be controlled. A simple example is presented to demonstrate how thermal and phase-transformation-induced strains cause dimensional changes and residual stresses. This example also serves as a representation of a typical "process model." The final sections of the article describe the state-of-the-art in heat treatment process modeling technology.

Design for Heat Treatment

William E. Dowling, Jr. and Nagendra Palle, Ford Motor Company

Overview of Component Heat Treatment

Component heat treatment is often the most cost-effective method for a manufacturing process to produce the desired material properties. (Detailed information about heat treating processes is provided in *Heat Treating,* Volume 4 of *ASM Handbook,* Ref 2.) However, in addition to material strength, heat treatment can result in the development of residual stresses (both compressive and tensile), dimensional changes (with respect to size and shape), and, in an extreme situation, component cracking, often referred to as quench cracking. These factors (residual stresses and dimensional changes) have the greatest influence on the design process of a component. Often, the inability to produce components with acceptable dimensions and residual stress patterns will cause changes in design, materials, and process selection leading to additional cost and lower material strength.

A typical component manufacturing process includes the following five steps, all of which can influence dimensional changes and residual stress patterns in heat-treated components:

1. Metalworking, machining, or other forming operations
2. Component heat-up
3. Hold at temperature for through-heating, solutionizing, or thermal chemical treatments such as carburizing or nitriding
4. Quenching from elevated temperature
5. Postquench tempering or aging treatment

Within these five process steps there are seven major factors that lead to size and shape changes and the development of residual stresses in heat treated components (Ref 3, 4):

- Variation in structure and material composition throughout the component, leading to anisotropy in properties and transformation behavior
- Movement due to relief of residual stresses from prior machining and forming operations
- Creep of the part at elevated temperature under its own weight or as a result of fixturing
- Large differences in section size and asymmetric distribution of material causing differential heating and cooling during quenching
- Volume changes caused by phase transformation
- Nonuniform heat extraction from the part during quenching
- Thermal expansion

All of these factors, except relief of prior residual stresses (second item) and creep at elevated temperature (third item), can be directly related to thermal and transformation-induced strains in the component. Residual stresses from forming operations can be reduced by stress relief prior to final shaping operations. Creep at elevated temperature can be addressed by appropriate component loading in the furnace. Neither of these two factors are directly associated with the design of the component. The other five factors are directly related to component design, and more precisely, strains introduced by transformations and nonuniform temperature distributions in the component. The relationship among design, material properties (yield strength at temperature, coefficient of expansion, thermal conductivity, etc.), and heating and cooling processes determine the distortion and residual stress patterns in heat treated components.

Thermal and Transformation-Induced Strains in Heat Treated Components

Thermal strain is developed in a component when differential thermal expansion (or contraction) occurs. The magnitude of strain is directly proportional to the thermal expansion coefficient of the material (α) and the temperature difference between two points (ΔT). This strain translates directly to a thermal stress σ_{th} (Ref 5):

$$\sigma_{th} = \alpha \Delta T E \quad \textbf{(Eq 1)}$$

where E is the elastic modulus of the material. However, if the thermally induced stress is greater than the flow strength of either the cooler or hotter material, permanent (plastic) deformation occurs. This plastic flow causes permanent shape change (distortion) and impacts the magnitude and distribution of residual stresses. Without plastic deformation, the component would return to its original dimensions once the part has thermally equilibrated. In addition to thermal strains, many materials systems undergo phase transformations as a function of temperature. Often, the new phase(s) that form have different volumes and different coefficients of expansion as well as different mechanical behavior(s) than the parent phase(s). These differences increase the complexity of understanding the effect of thermal gradients on strains produced and the resulting plastic deformation.

Example: Thermal and Transformation-Induced Strains in a Large, Thick Plate.

This simplified example demonstrates how thermal and transformation-induced strains can result in substantial plastic deformation and residual stresses. A large, thick plate (Fig. 1a) has a very thin layer uniformly heated from room temperature to 850 °C and then cooled. It is assumed that the bulk of the material is unheated and does not strain because of its much greater thickness. The heating and cooling processes can be broken down into 6 segments (shown schematically as A to F in Fig. 2; key process points are labeled 1 to 7). During the heating and cooling cycle, the thin layer of heated material will undergo a phase transformation from phase 1 to phase 2 upon heating and from phase 2 to phase 3 upon cooling. The thermal profiles through the sample for process point 4 is shown in Fig. 1(b) to illustrate that the heated layer is considered to be at the same temperature all the way through, with a thermal step change from the heated layer to the unheated bulk.

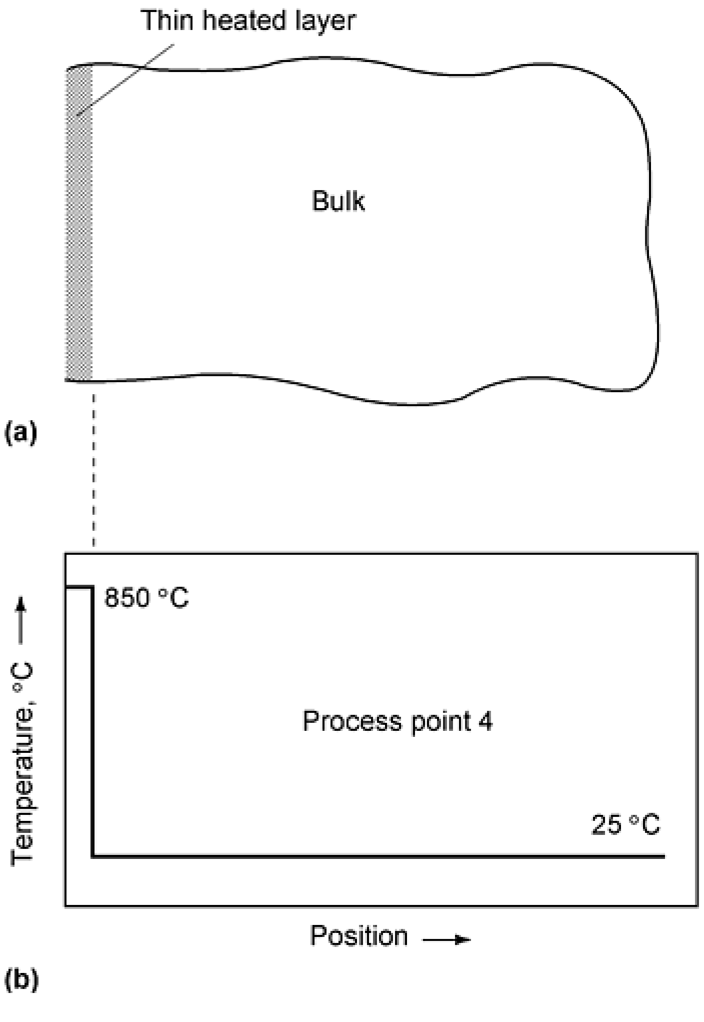

Fig. 1 Schematic (a) of a large, thick plate and assumed temperature distribution (b) at process point 4 (Fig. 2)

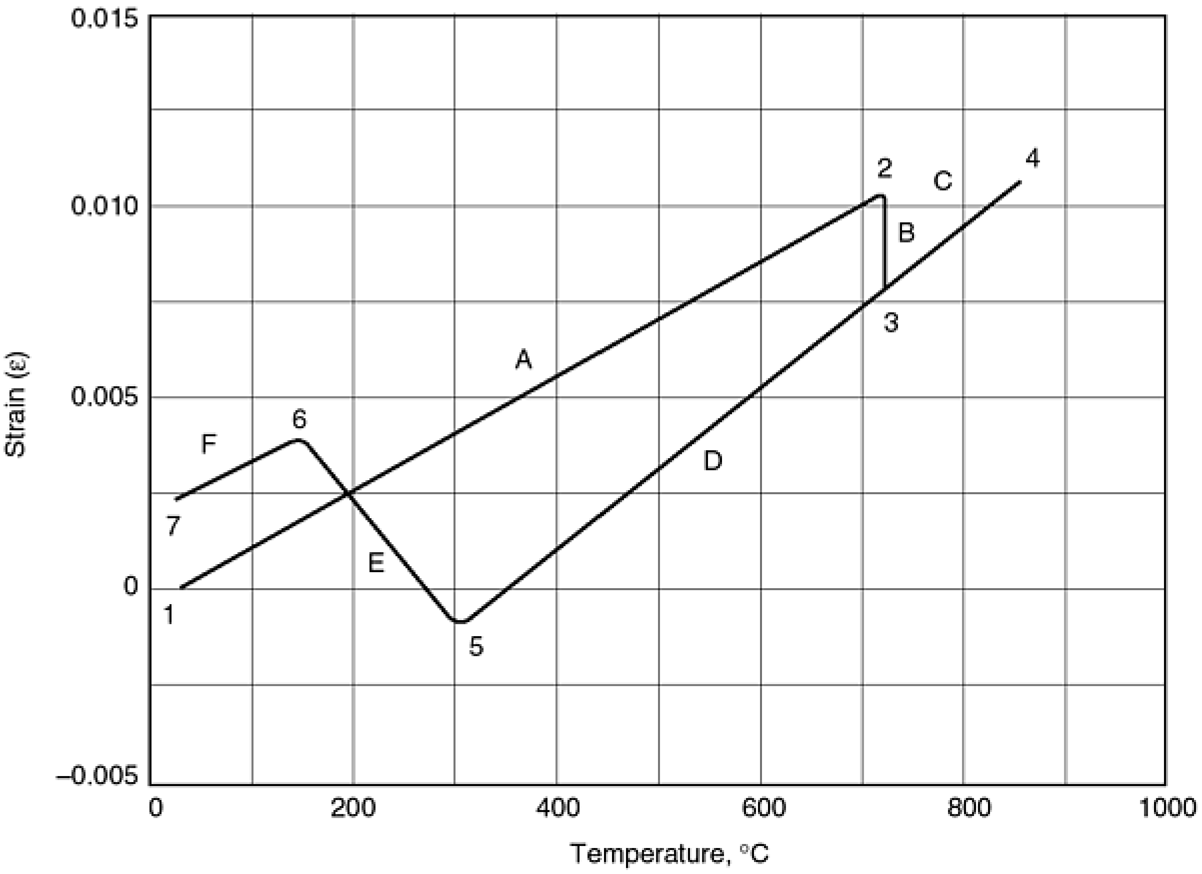

Fig. 2 Strain history during heating and cooling for a large, thick plate. See text for discussion of the labeled process segments.

The strain produced by thermal ($\alpha\Delta T = \varepsilon_{th}$) and transformation ($\varepsilon_{tr}$) strain is calculated for each segment identified in Fig. 2. The total induced strain must be accommodated in the thin layer through either elastic (ε_{el}) or plastic (ε_{pl}) strain, which sums to the total strain:

$$\varepsilon_t = \varepsilon_{th} + \varepsilon_{tr} = -(\varepsilon_{el} + \varepsilon_{pl}) \quad \textbf{(Eq 2)}$$

The induced strain and the accommodation strain must equalize in the thin layer because the assumption has been made that the bulk material will not accommodate any strain. The values for α(thermal expansion coefficient) for phases 1, 2, and 3 are chosen to be 15, 21, and 13 × 10^{-6}/°C, respectively, and are assumed to be independent of temperature for this example. The transformation strains chosen are $\varepsilon_{tr\ 1\text{-}2}$ = 0.0025 for the transformation from phase 1 to phase 2 at 725 °C and $\varepsilon_{tr\ 2\text{-}3}$ = 0.0075 for the transformation from phase 2 to phase 3 over the temperature range 300 to 150 °C.

In order to determine the accommodation strain values, Young's modulus (E), and the yield strength (σ_{ys}) are required as a function of phase and temperature; the data for this example are shown in Fig. 3. For simplicity, the flow behavior is assumed to be elastic-plastic in nature with no work hardening. Thus, the yield strength is the flow stress at any plastic strain level.

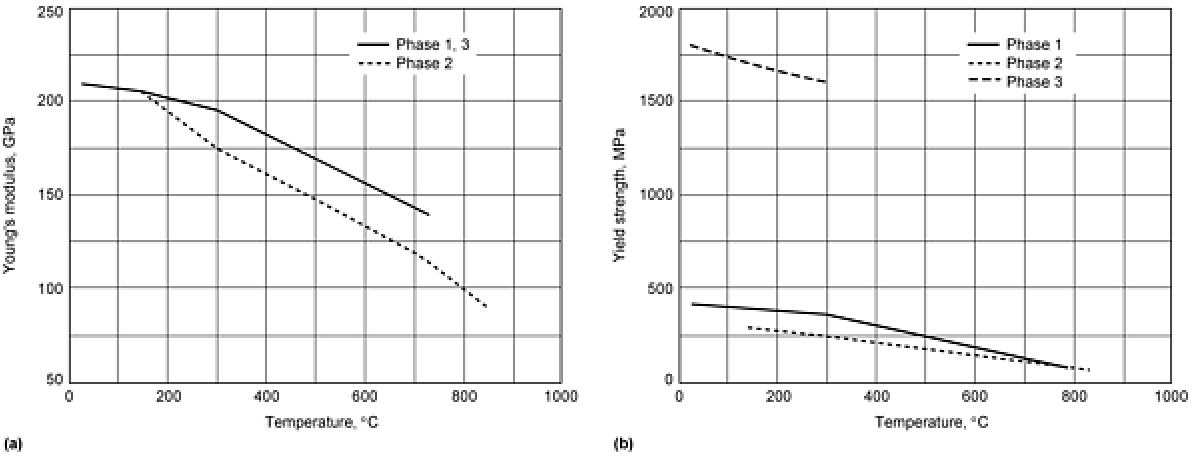

Fig. 3 Young's modulus (a) and yield strength (b) as a function of phase and temperature for the large, thick plate example

The total strain and how it is accommodated is described below for each segment of the thermal cycle shown in Fig. 2.

Segment A. The thin layer is heated from 25 to 725 °C without phase transformation. This heat-up induces a linear thermal strain of $\alpha\Delta T(\varepsilon_{th})$ that equals 0.0105. However, the thin layer is constrained by the bulk and is not allowed to expand. This constraint produces a compressive stress in the heated layer equal to the flow stress of the material. This compressive stress accommodates the elastic strain, with the remaining applied strain accommodated through plasticity in the heated layer. For cases in which the yield strength of the material is exceeded, the strain distributions follow the relationship:

$$\varepsilon_{el} = (\sigma_{ys} + \sigma_{old})/E \text{ or } \varepsilon_{el} = (\sigma_{ys} - \sigma_{old})/E \quad \textbf{(Eq 3)}$$

The stresses are additive if the stress from the prior history, σ_{old}, is in the opposite direction of the new stress. The difference in the stresses must be taken if the prior history stress and the new stress are the same direction. The results are shown in Table 1.

Table 1 Material condition at each stage in the thermal cycle shown in Fig. 2

Process segment (Fig. 2)	Temperature range, °C	Phase transformation	Total strain (ε_t)	Accommodation strain		Phases	Remaining stress, MPa	Yield strength, MPa
				ε_{el}	ε_{pl}			
A	25-725	No	0.0105	-0.0007	-0.0098	Phase 1	-100	100
B	725	Yes	-0.0025	0.0017	0.0008	Phase 2	100	100
C	725-850	No	0.0026	-0.0017	-0.0009	Phase 2	-50	50
D	850-300	No	-0.0116	0.0017	0.0099	Phase 2	250	250
E	300-150	Yes	0.0050	-0.0050	None	Phase 2 + phase 3	-775	1700

Segment B. The thin layer undergoes a complete phase transformation from phase 1 to phase 2 with no temperature change, resulting in a transformation strain of -0.0025 and no thermal strain (Fig. 2). This results in a stress reversal, which causes the heated layer to be in tension. The magnitude of the transformation strain is sufficient to cause the yield strength of phase 2 to be exceeded and induce a plastic strain of 0.0008.

Segment C. The layer is heated from 725 to 850 °C, causing a thermal strain of 0.0026. This again reverses the stress back to compression in the thin layer and causes a compressive plastic strain of -0.0009.

Segment D. Heating is stopped and the layer uniformly cools from 850 to 300 °C. This causes contraction inducing a thermal strain of -0.0116. This strain accommodation is broken down into 0.0017 elastic and 0.0099 plastic. The resulting deformation is predominantly plastic because of the low yield strength (250 MPa) of phase 2 at 300 °C and its high modulus (175 GPa).

Segment E. The layer is cooled from 300 to 150 °C. During this period, a phase transformation occurs from phase 2 to phase 3 that causes an expansion strain of 0.0075. In addition, a thermal contraction of -0.0025 occurs. The thermal strain was determined by averaging the expansion coefficients. The net total strain was 0.0050. However, phase 3 has a much higher yield strength than phase 2, and this strain is all accommodated elastically. The resultant residual stress at 150 °C is -775 MPa.

Segment F. The final stage of the process is a cooling from 150 to 25 °C. This is all thermal contraction strain, which reduces the compressive residual stress to -440 MPa.

Conclusions. A summary of the results from this example is shown in Table 1. Most of the plastic deformation occurred during the heat-up and cool-down stages of the process. This was largely the result of the low strength of the material at high temperature and the low strength of phase 2 at lower temperature (300 °C). A substantial residual stress was produced mainly from the expansion during the final phase transformation and the simultaneous change to a high-strength material. This example problem is a simplistic representation of surface hardening of steel, which usually produces a large compressive stress at the surface.

From this example, it is readily seen that even for a simple problem, a substantial plastic deformation and a substantial residual stress can result from heat treat processes. During the actual quenching of a complex part, not only can similar transitions in phases and phase strengths happen, but the thermal distribution can vary greatly depending on the component geometry and the heat treating process.

---

Component Design for Heat Treating: Experience-Based Design Rules

Several general experience-based design guides have been developed (Ref 5, 6, 7, 8, 9). They are all based on the concept of minimizing nonuniform heating and cooling of components. Large thermal gradients and thermal asymmetry produce distortion and have the potential of causing tensile stresses and thus cracking of the component. The concept of reducing the opportunity for large thermal gradients to minimize distortion is counter to the need for rapid quenching in order to form martensite in steel or to prevent precipitation after solution treatment of age-hardenable materials. The preferred method is to quench the material only as rapidly as absolutely necessary to form the desired phase(s). Optimization of this manufacturing system is a combination of material selection, heat treatment process, and component design for heat treatment. This optimization necessitates that the heat treater work in conjunction with the designer to avoid geometric features that can be difficult to heat treat and aid in the selection of appropriate heat treat processes.

Over the years, some basic rules have been developed for component design for heat treatment; these are summarized below.

Design the Component To Be As Symmetrical As Possible. Part asymmetry causes asymmetrical thermal and transformation gradients, which often result in nonuniform plastic deformation and distortion. A classic example of this is shown in Fig. 4 for the carburizing and quenching of a gear (Ref 6). The thinner section in the web cools more rapidly than the gear section. As the web section contracts the gear section is in circumferential compression. Then, as the gear

section cools and contracts, the web restricts uniform contraction because it is not centered. This results in a tapered gear. The problem can be resolved by offsetting the hub, or ideally, by making the gear symmetrical.

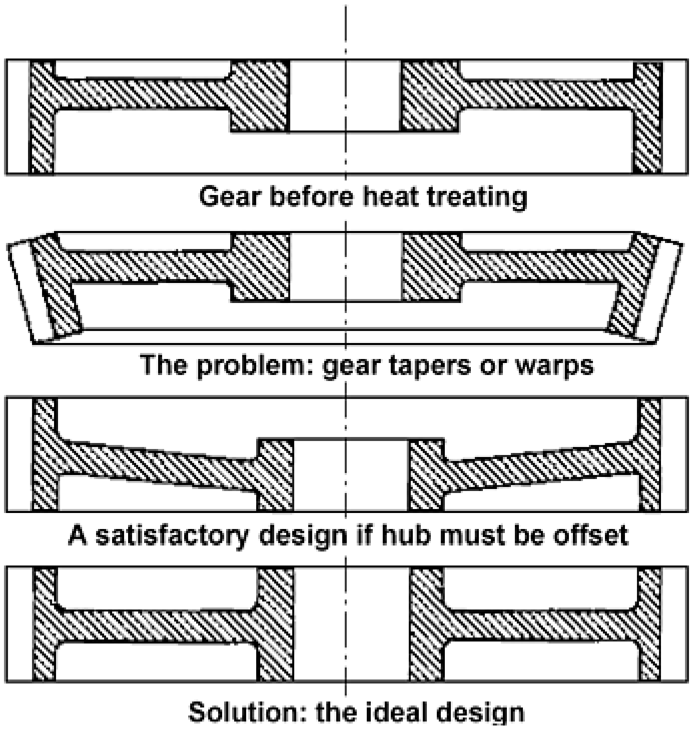

Fig. 4 A typical problem caused by lack of symmetry in design, illustrated by a gear that warped during heat treating. Design modifications can solve the problem. Source: Ref 6

Maintain Uniform Section Thicknesses. Large changes in section thickness cause large thermal gradients during both heating and cooling. If these section changes are abrupt they will act as strain concentrators causing distortion. Figure 5 shows the result of placing large holes in the web of a gear to reduce weight. If the holes are too large they cause flat spots on the gears. A general rule that has been developed is to keep the diameter of such holes to no more than one-third the web width.

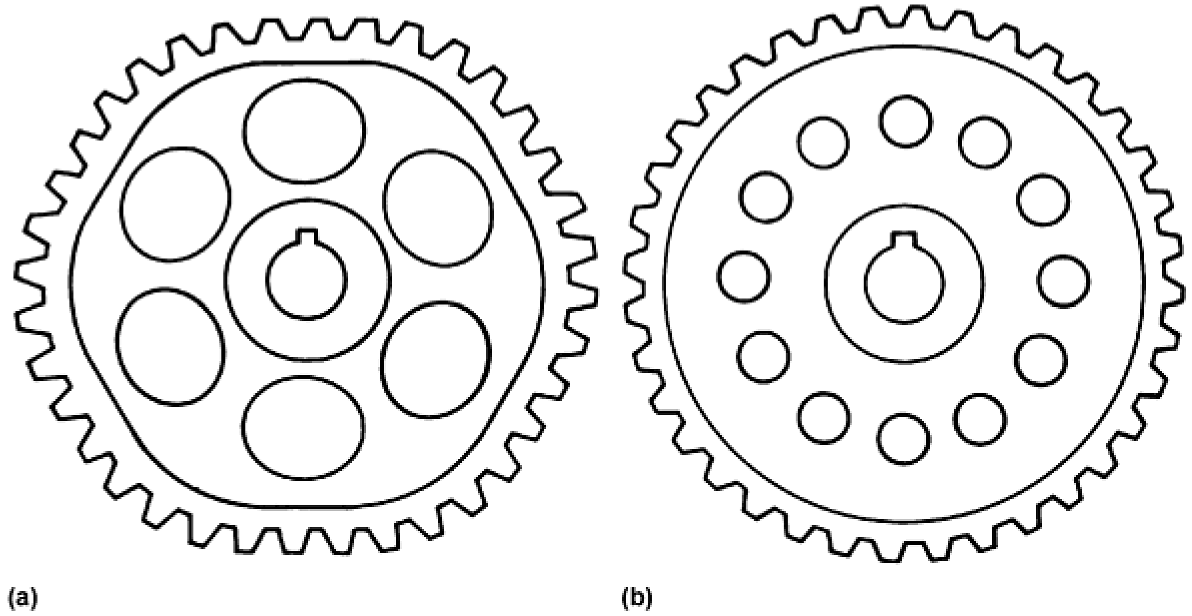

Fig. 5 Problem caused by the use of holes to reduce weight of a gear. (a) If the designer specifies large holes in the web, heat treatment may produce a flat spot for each hole. (b) Keeping the hole diameter to one-third of the web width eliminates the problem. Source: Ref 6

Minimize Holes, Deep Splines, and Keyways. These features often destroy the symmetry of the component and act as strain and stress concentrators during heat treatment. In addition, these features can entrap vapor resulting in slower local cooling rates, making it difficult to effectively quench the component. If they must be used, small radii at the corners of keyways should be avoided and spline transition should be gradual.

Avoid Sharp Corners. Corners should be designed with as large a radius as possible. If sharp corners cannot be avoided, it is good practice to provide relief notches in place of sharp edges (Ref 5).

Avoid Long, Thin Sections. The definition of "long, thin section" varies and depends greatly on quenching media; however, any section length greater than 15 times the diameter is almost always characterized as such and the slightest nonuniformity in quench will cause it to distort. As the quenching medium becomes more severe (i.e., water, caustic quench), this criterion is reduced to as low as 5 times the diameter (Ref 7). For larger length-to-diameter ratios, consideration should be given to fixture quenching or induction hardening.

Beware of Part Complexity. The current trend leans toward placing more individual components together to make a single part or toward adding many geometric features to a part in order for the component to serve several functions. This can often lead to improved package efficiency or reduced cost in other stages of the manufacturing process (see the article "Design for Manufacture and Assembly" in this Volume). However, the component may become more difficult to heat treat, especially if the design rules mentioned above concerning uniform section thickness, symmetry, and the avoidance of holes and keyways are violated.

All these simple rules are intended to encourage designers to produce component designs that are readily heat treatable. However, components will continue to be designed that are asymmetrical, have nonuniform sections, and contain many features. When faced with such components, heat treaters must use their experience to find solutions to the problem. Analytical solutions to improve designing for heat treatment are on the horizon with the development of finite element approaches to simulation and with the vast improvements in computer power that are occurring every day.

Computer Modeling as a Design Tool for Heat Treated Components

A computer process simulation model allows a particular design to be tested under a specific set of process conditions. The computer software can graphically display not only the resulting residual stresses and distortions in the component, but also the associated transient evolution of temperature, metallurgical phases, volume changes, and stresses. These analytical models can be used for point-by-point comparison (with experiments) and to view distributions of quantities

such as residual stresses or phases throughout the part. Based on the transient response of the component design to the specified process, design parameters and processing conditions can be adjusted so as to minimize the undesirable outcomes that are predicted. Of course, like any analytical tool, accuracy and confidence in the modeling technique is of utmost importance. There are inherent inaccuracies in any computational technique, and the user of the process model must be aware of the limitations as well as the strengths of the model. Given the state-of-the art of these modeling techniques, qualitative results are probably the most valuable product of process modeling.

The thermal and transformation strain example described in a previous section is in fact a process model that includes the various transformations that a point in the material undergoes during heat treatment and the associated changes in dimensions and stress patterns. The example illustrates how the various stages of transformation that a material experiences can be analytically described (or modeled!). It is important to realize that all the changes in the thin section of the plate are caused by the imposed thermal profile, which in turn results entirely from the "process" conditions that the plate experiences. The process conditions usually include the furnace atmosphere (for example, temperature and carbon potential), heating rates, and quench conditions. Modeling of heat treat processes, like other materials processes such as casting and welding, is quite complex due to the tight coupling of various metallurgical transformations and the associated changes in thermal and mechanical states.

A process simulation model is usually exercised for a specific material and a specific process. Both the material and process characteristics are inputs to the model. The process specifics manifest themselves in "initial" conditions (e.g., temperature of the component at the start of heat treatment) and boundary conditions (e.g., the quench temperature and level of agitation in the bath) of the model. The material properties needed are the modulus, strength, coefficient of thermal expansion, yield strength, conductivity, specific heat, and density. Because the material undergoes drastic changes in temperature, these properties should be temperature and phase dependent. It is extremely important for the user to have accurate information relating to these data, thus generating this information often requires extensive characterization of the material and process under consideration.

The thin section in the example experienced several different stress states primarily because the yield strength of the material changed depending on the temperature and phase. Also, for materials such as the one illustrated, accurate transformation kinetics are required to identify the phases present anywhere in the component at any time in the process. The solvers (using finite or boundary element or finite difference techniques; see the article "Finite Element Analysis" in this Volume) are used to solve thermal and structural governing equations subject to the specified boundary conditions and material characteristics. A comparison of typical experimental and simulation procedures is shown in Fig. 6. Typically, each of the five steps of the heat treat process (described in the section "Overview of Component Heat Treatment" in this article) represents a computer analysis. For example, carbon diffusion during a carburizing process requires a mass diffusion analysis, the heat-up in the furnace requires a thermal analysis, and the quenching requires a thermal and structural analysis. Some of these analyses depend on each other very closely, leading to "coupled" analyses.

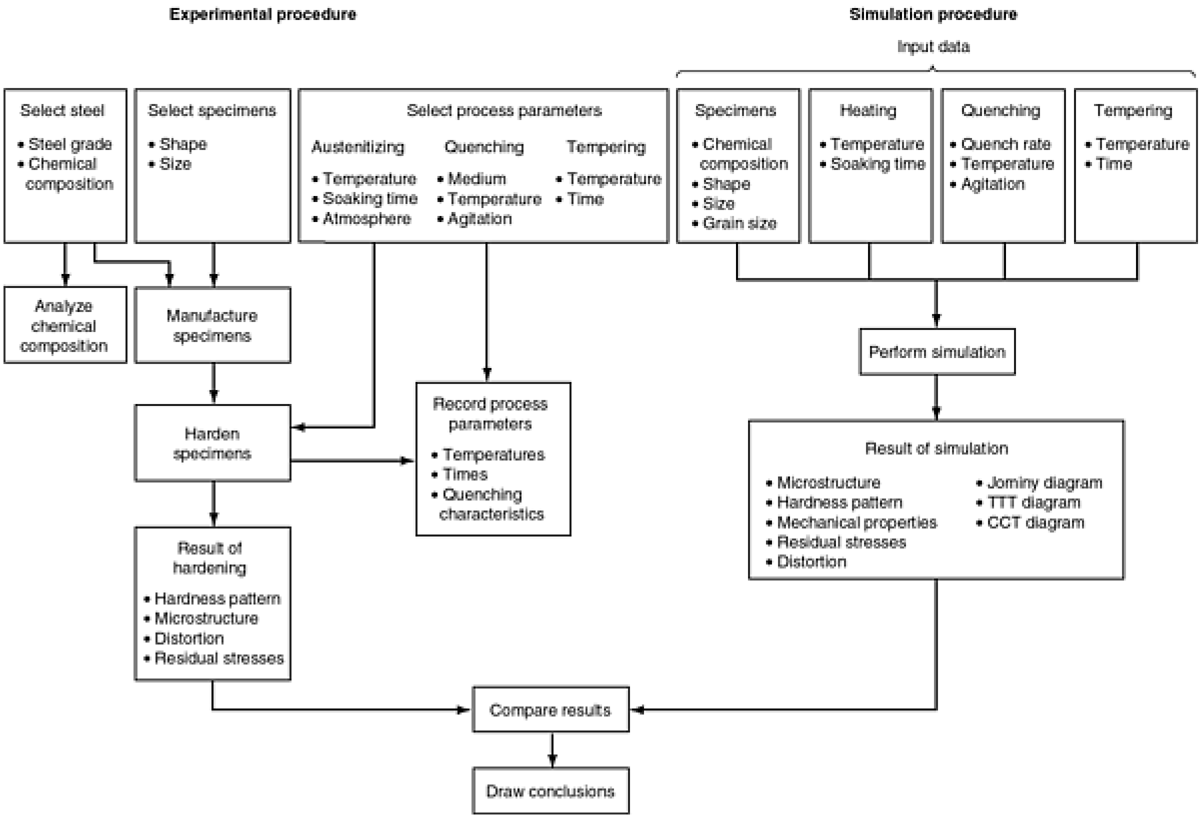

Fig. 6 Comparison of experimental and simulation procedures for heat treat design. Source: Ref 10

All seven of the factors that lead to size and shape changes and the development of residual stresses (listed in the section "Overview of Component Heat Treatment" in this article) can be input into (or output from) the model. The variation in structure and composition, the differential heating and cooling, and the quench agitation can be included in the model using "initial" and "boundary" conditions. The movement due to stress relief, the creep of the part under its own weight, the volume changes due to phase transformation, and thermal expansion can be output from the model based on the boundary conditions and material description.

A typical process model, such as one for heat treatment, has several major aspects to it. A process model for a carburizing process is shown in Fig. 7. The flow chart shown in Fig. 7 represents the different pieces of a simulation tool that are used to analyze the carburizing process. The part geometry represents the initial design. If the solver is finite element based, the geometry has to be discretized into a finite element mesh (see the article "Finite Element Analysis" in this Volume). The various constituents in the model are described below.

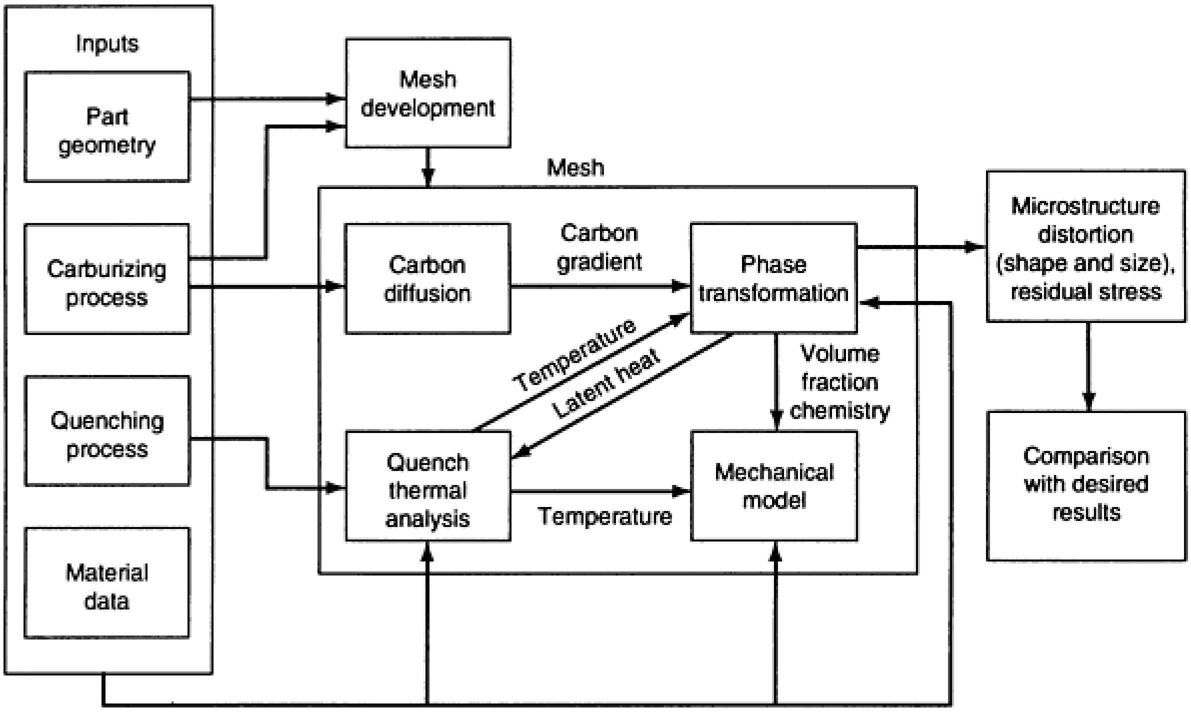

Fig. 7 Process model for a carburizing problem. Source: Ref 11

Boundary conditions represent the process conditions under which the part is being heat treated. To simulate a carburizing process, the carburizing cycle parameters constitute the boundary conditions. These are expressed using a surface carbon potential as a function of time and temperature. To simulate a quenching process, convection boundary conditions are used to describe the part-quench interface. Heat transfer coefficients for a water quench and oil quench are shown schematically in Fig. 8. Some examples for salt quenches are given in Ref 12. These values of heat transfer coefficients are typical for small parts in a large quench tank. The boundary conditions are extremely important because they represent the uniqueness of a particular part (and quench). Extensive experiments are sometimes required to estimate these boundary conditions. Occasionally, the supplier of the quenchant can also provide information about the rate of heat removal from a part surface for a particular quench.

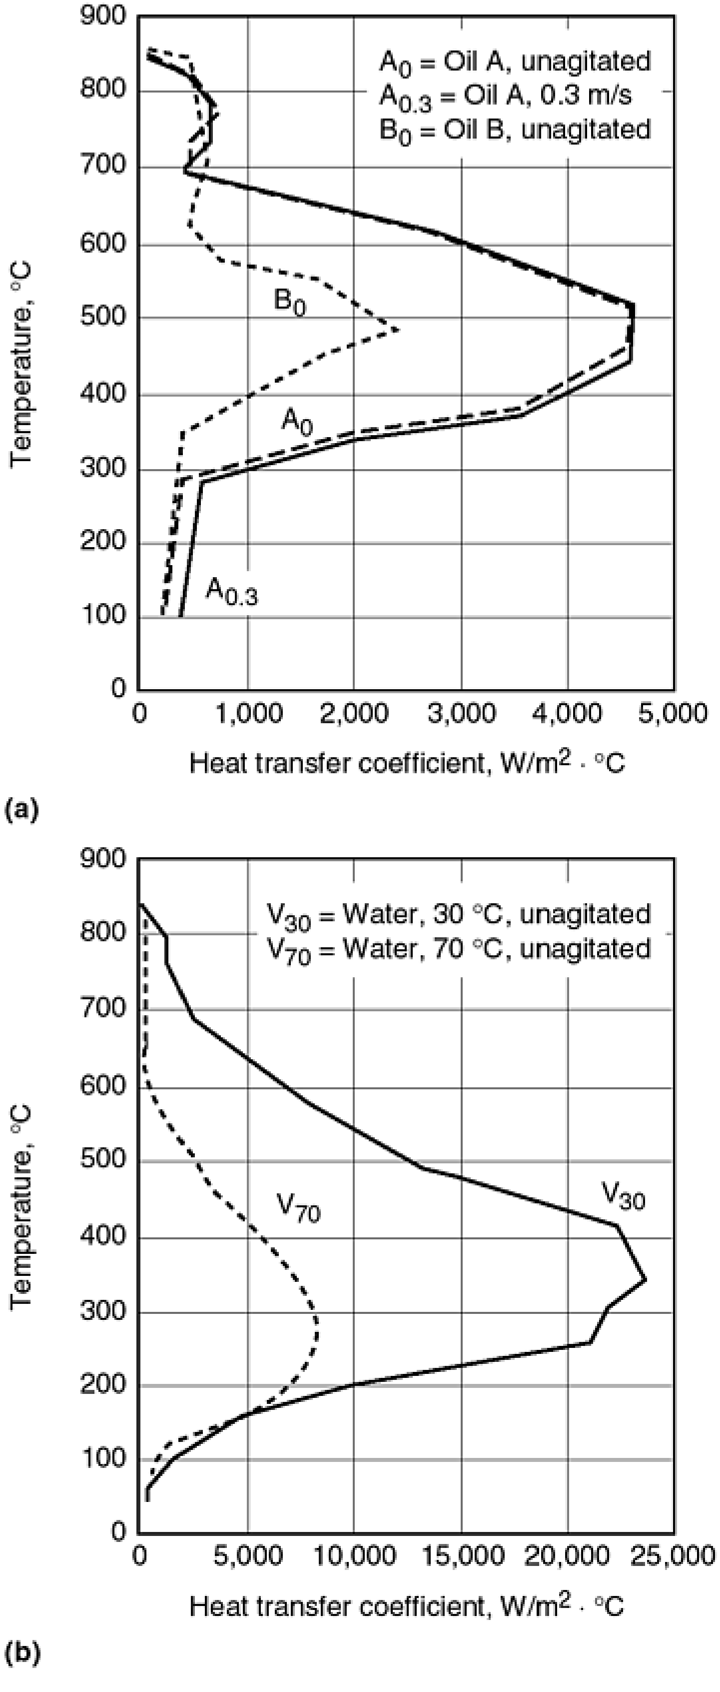

Fig. 8 Example of heat transfer coefficient boundary conditions for oil and water quenches. Source: Ref 10

The deformation model (stress-strain relationships) used for computing distortion and residual stresses requires an accurate description of the phase transformation kinetics and the associated microstructure and volume changes. The deformation model uses the temperature- and phase-dependent mechanical properties to determine the deformation

changes, given the temperature changes. These volume changes (e.g., from austenite to martensite) typically lead to transformation-induced plasticity (TRIP). This is caused by a soft phase (such as austenite) being deformed by a harder phase (such as martensite) during the transformation. Several deformation models have been developed with reasonable success (Ref 13). Implementation of these models requires a good understanding of mechanics of the materials. The close interaction between various parameters in the deformation model is referred to as "metallo-thermo-mechanical" coupling. Figure 9 shows the various couplings considered in the modeling of phase transformations during the heat treatment of steels.

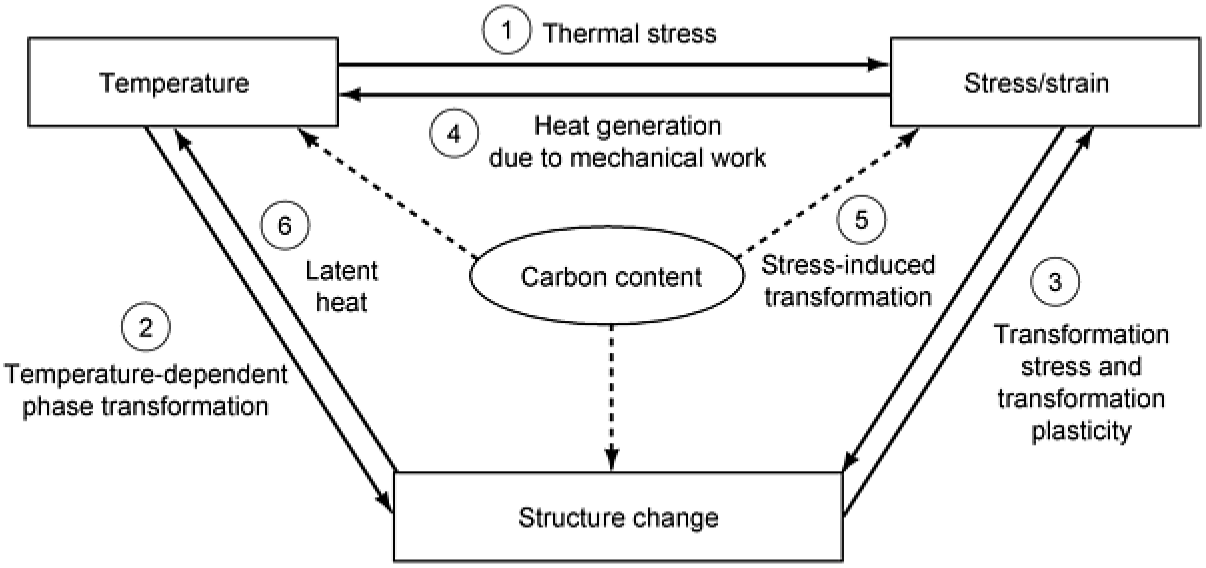

Fig. 9 Phenomenological coupling in heat treat simulation. Source: Ref 14

Analysis Software. An analysis package capable of performing thermal and structural analyses is required to execute the process model. This analysis package should integrate not only the above-mentioned pieces, but also provide tools to graphically display the thermal and phase evolution, the final size and shape of the part, and the resulting residual stresses. This information can be used by the process engineer to make either a design or process change recommendation. From a practical standpoint, even if the computer model is not completely accurate, the analysis tool can be used to perform sensitivity studies to understand which process or material parameter has the greatest (or least) impact on the resulting part distortion or residual stress. Examples of commercial software systems capable of performing heat treatment analyses are HEARTS (Ref 14), TRAST, and MetalCore (Ref 15). TRAST is a deformation model written in the form of a FORTRAN user subroutine that has to be used with ABAQUS (Ref 18). TRAST is based on some original work carried out by Sjostrom at Linköping University in 1982 (Ref 17). Another software system will result from a collaborative effort under the auspices of the National Center of Manufacturing Sciences (Ref 18).

The examples presented in these references represent the state-of-the art in the area of modeling of heat treatment processes. Several open issues need to be resolved before computer modeling of heat treat processes becomes routine. Much needs to be done in the areas of numerical analysis, material characterization and modeling, quench tank characterization, and prediction of phase transformation behavior. However, successes demonstrated in recent literature show that heat treatment modeling is very much a viable technology.

Design for Ceramic Processing

Victor A. Greenhut, Rutgers--The State University of New Jersey

Introduction

THE CERAMICS AND GLASSES INDUSTRY has estimated annual sales of between $100 and $200 billion worldwide. Ceramic production accounts for about 45% of the entire world market for manufactured ceramics and glasses, not including cements and ceramic powders. One estimate of ceramic sales in various categories and subcategories is provided in Fig. 1; Fig. 2 provides an alternative estimate. It may be noted that dollar values differ in several categories. This is for two reasons. First, the market is rather fragmented with production ranging from large corporations to individual artisans. Much production activity is conducted within the industry for internal consumption. Low estimates tend to count only larger-scale industrial activity, while higher values attempt to include the small-shop and internal-company production. Second, there are significant overlaps between various categories--for example, electrical porcelains might be included with technical ceramics or whitewares. From the data of Fig. 1 and 2 it can be seen that the major fraction of ceramics produced include clay (as well as beneficiated and/or chemically derived materials) among their raw materials. For this reason, the discussions of materials and process design first concentrates on these materials.

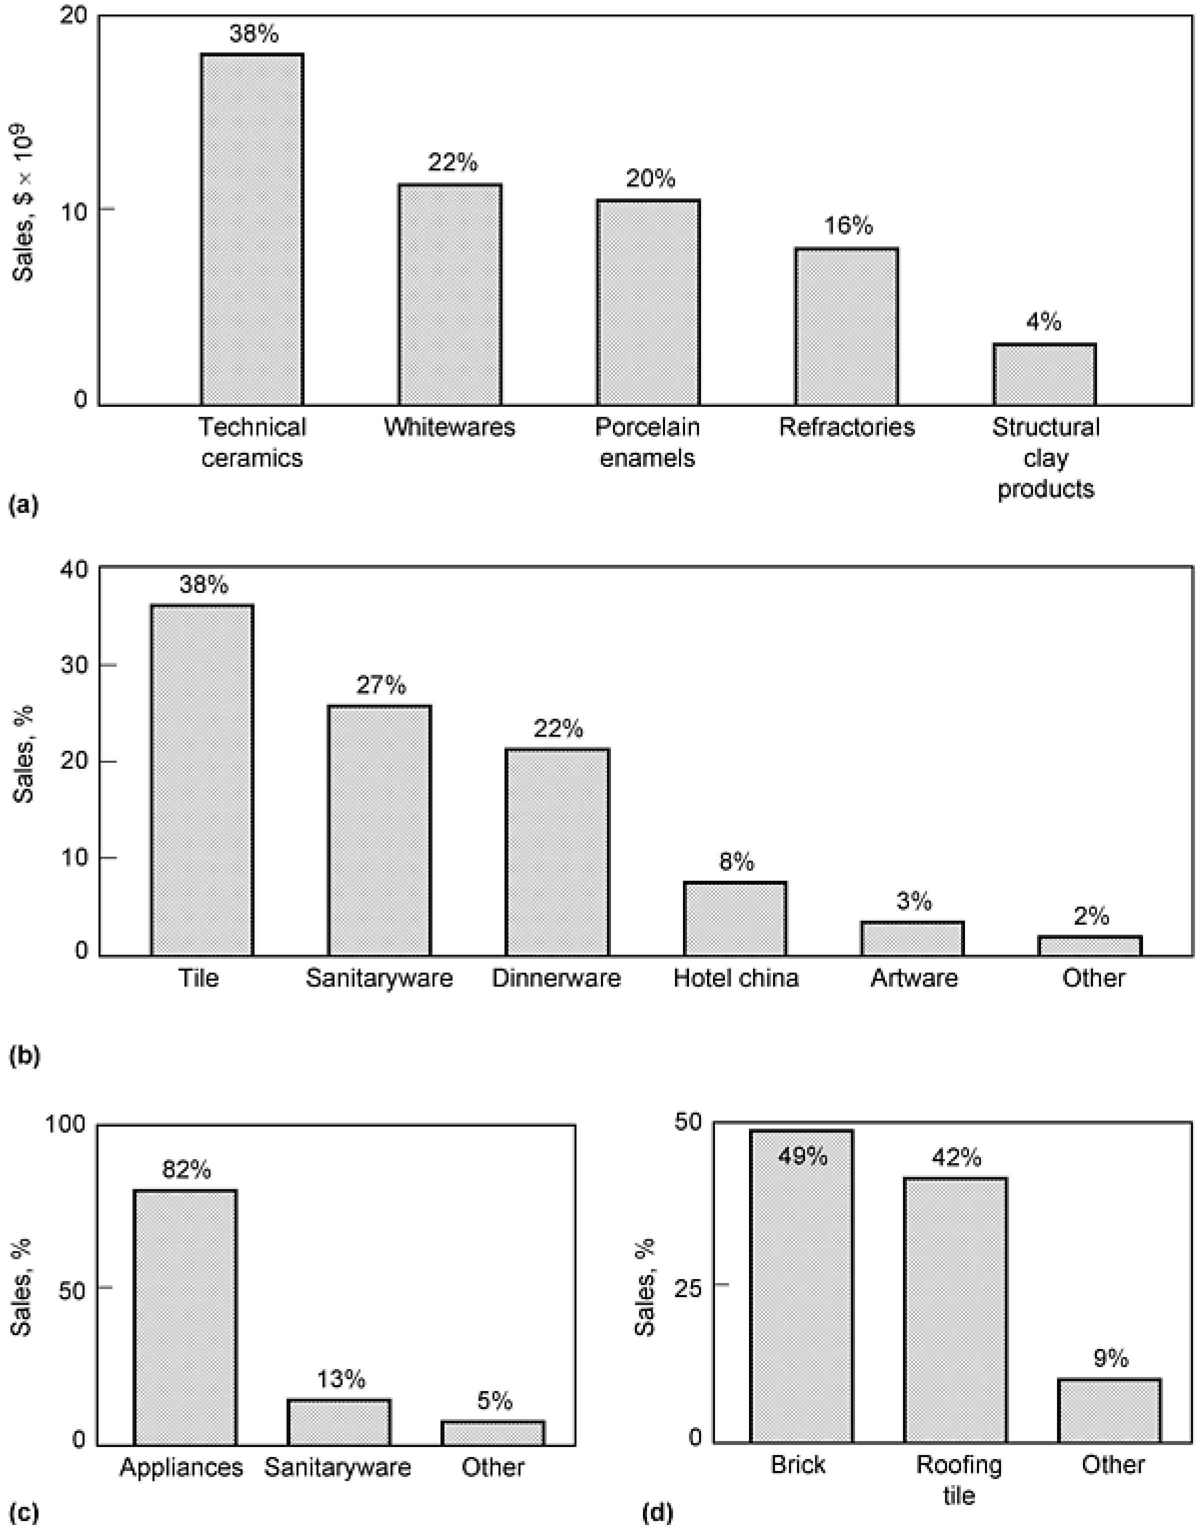

Fig. 1 Estimated worldwide sales of ceramics. Does not include sales of glass products, which is estimated to be approximately $58 billion (1996). (a) Sales of traditional/industrial ceramics (1996). (b) Distribution of whiteware sales (1992). (c) Distribution of porcelain enamel sales (1992). (d) Distribution of structural clay products sales (1992). Source: Ref 1, 2, 3

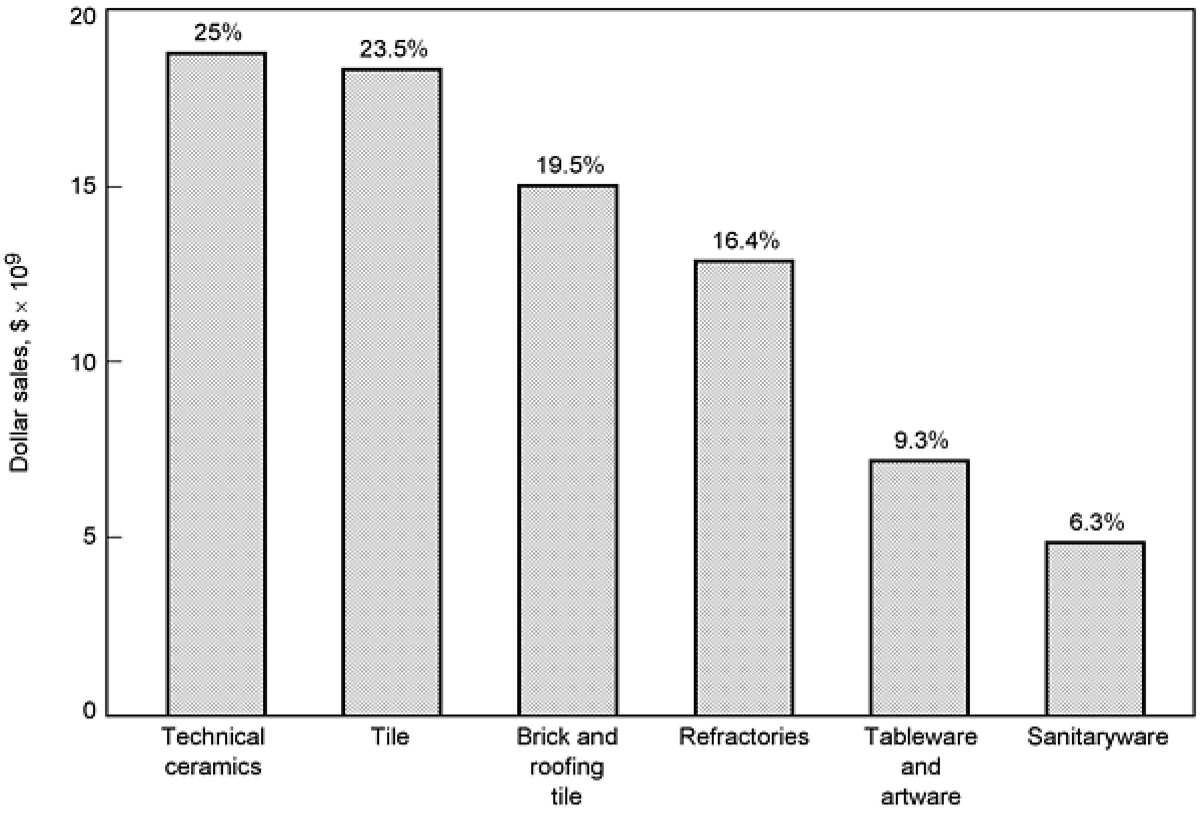

Fig. 2 Estimated worldwide sales of traditional/industrial ceramics (1992). Source: Ref 1, 2, 3

Many technical ceramics contain clay as part of their formulation, but tend to employ a higher proportion of high-purity, processed, or derived raw materials. Most refractory brick and parts are processed similarly to the clay-based systems. Technical ceramics include oxide and nonoxide materials used for a number of industrial applications such as electrical porcelains, electronic substrates, wear parts, and chemically resistant parts. It also includes advanced ceramics providing particularly demanding performance in engine parts, biomedical prostheses, high-temperature bearings, industrial cutting tools, and so forth. Such materials are estimated to account for as much as 5% of ceramic sales. Consideration in this article is given to some of the special issues in process design and materials selection for those technical ceramics that differ from clay-based systems. The article "Effects of Composition, Processing, and Structure on Properties of Ceramics and Glasses" in this Volume provides a brief discussion of many of the plastic cements (monolithics, gunning mixes, ramming compounds) that are applied and fired in situ. These materials are not discussed here. Neither are porcelain enamels, which are chiefly composed of glass frit (fine particulate) and combine glass technology with metal-coating methods. Detailed information about all major types of these materials can be found in *Ceramics and Glasses,* Volume 4 of the *Engineered Materials Handbook.*

This article provides an overview of the processing steps used in ceramics processing and related mechanical design considerations. The breadth of the topics presented prevents a detailed discussion of each. A wide variety of products and ceramics compositions are represented. The references listed at the end of this article provide more detailed information about ceramics processing issues.

Design for Ceramic Processing

Victor A. Greenhut, Rutgers--The State University of New Jersey

Costs

The production of ceramic products covers a broad spectrum of materials and applications manufactured by facilities that vary over a broad scale. Contrast the production of brick and tile at hundreds of tons per employee each year with the exclusive art of an artisan potter or the special-purpose advanced ceramic valves for a racing car. All ceramic production is capital intensive. The required equipment for materials handling, grinding, mixing, forming, drying, firing, and suitable packaging necessitates a relatively large investment in capital equipment and physical plant at any scale. Long-term investment strategies are necessary. Large-scale production is undergoing major change in terms of automation, controls, and continuous processing, which require flexible plant and equipment selection and design to anticipate future developments.

In order to examine the various factors in production, the manufacture of tile will be used as a model. Tile is chosen both because it has a substantial level of production (see Fig. 1 and 2) and because the economics of tile manufacture has been examined over the past two decades as automated tile manufacture became a major industrial trend. This approach to continuous tile production initiated chiefly in Italy. Figure 3 shows the typical distribution of costs in 1971, before significant automation, and in 1989, when most of the Italian tile manufacturing was highly automated. The graph is for an indexed Lira (It). Figure 4 shows the relative change in costs per square meter of tile. The net result of automation was a 30% reduction in cost per square meter, a tripling of productivity per employee, and a 150% increase in production above the 1971 level. The sales price of tile decreased by about 15%, due in large part to an increase in the total market (competition with other surfacing materials) and capture of a greater international market share. It is clear that automation of tile manufacture has led to improved manufacturing practice at a reduced cost. The capital investment in an automated facility is similar to conventional operations. The technology has now been implemented worldwide in turnkey tile plants "exported" from Italy.

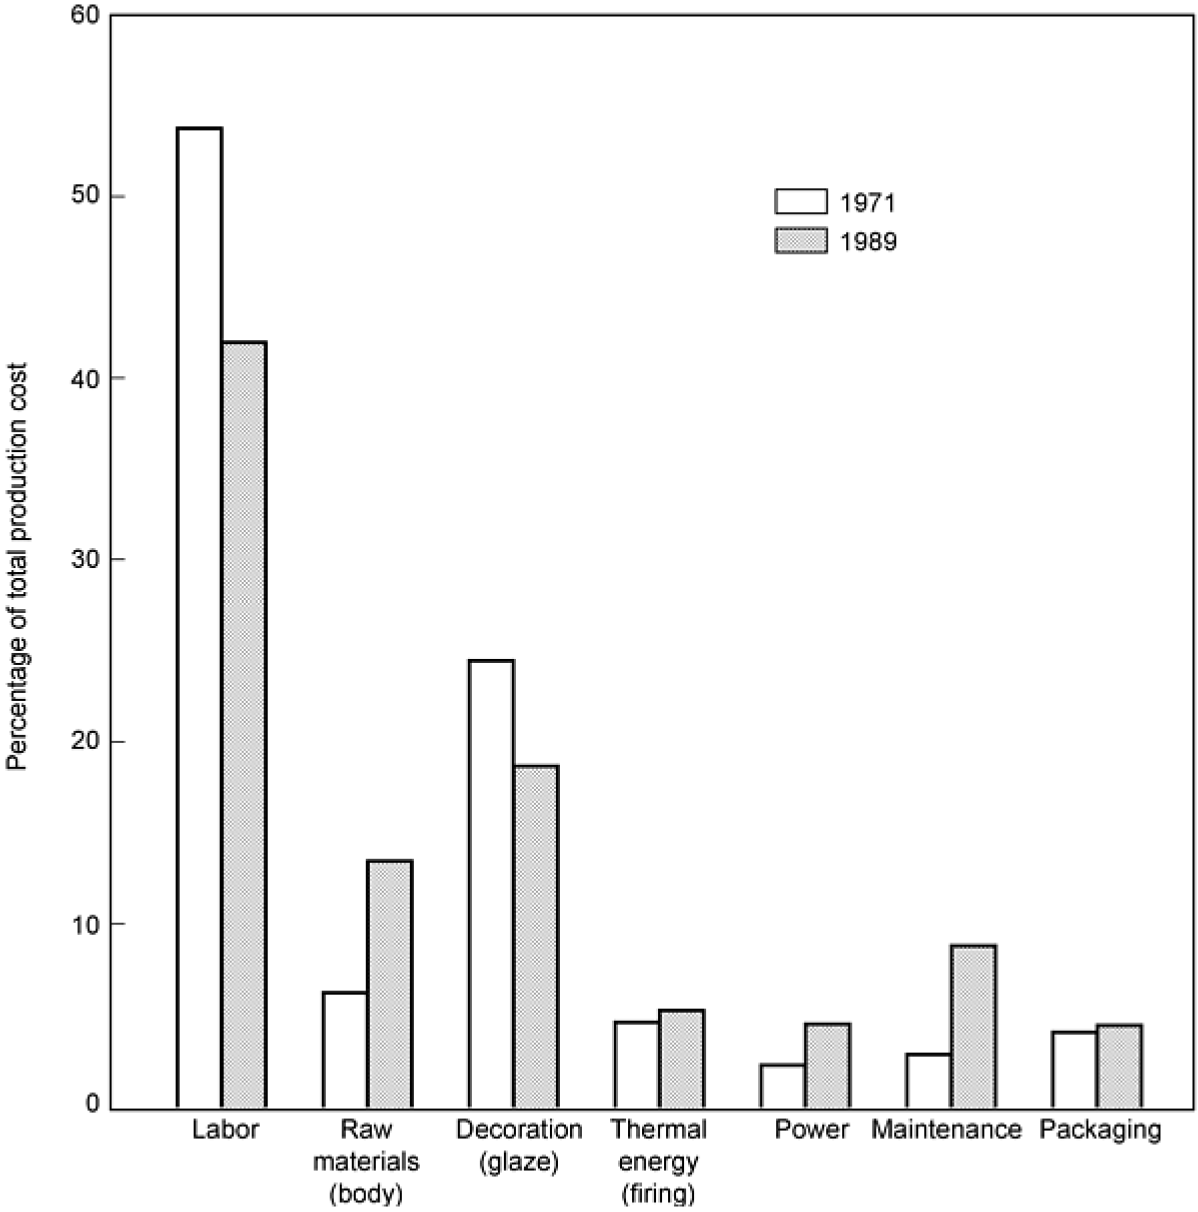

Fig. 3 Change in costs of Italian tile production 1989 versus 1971 (square meter basis). Source: Ref 1, 2, 3

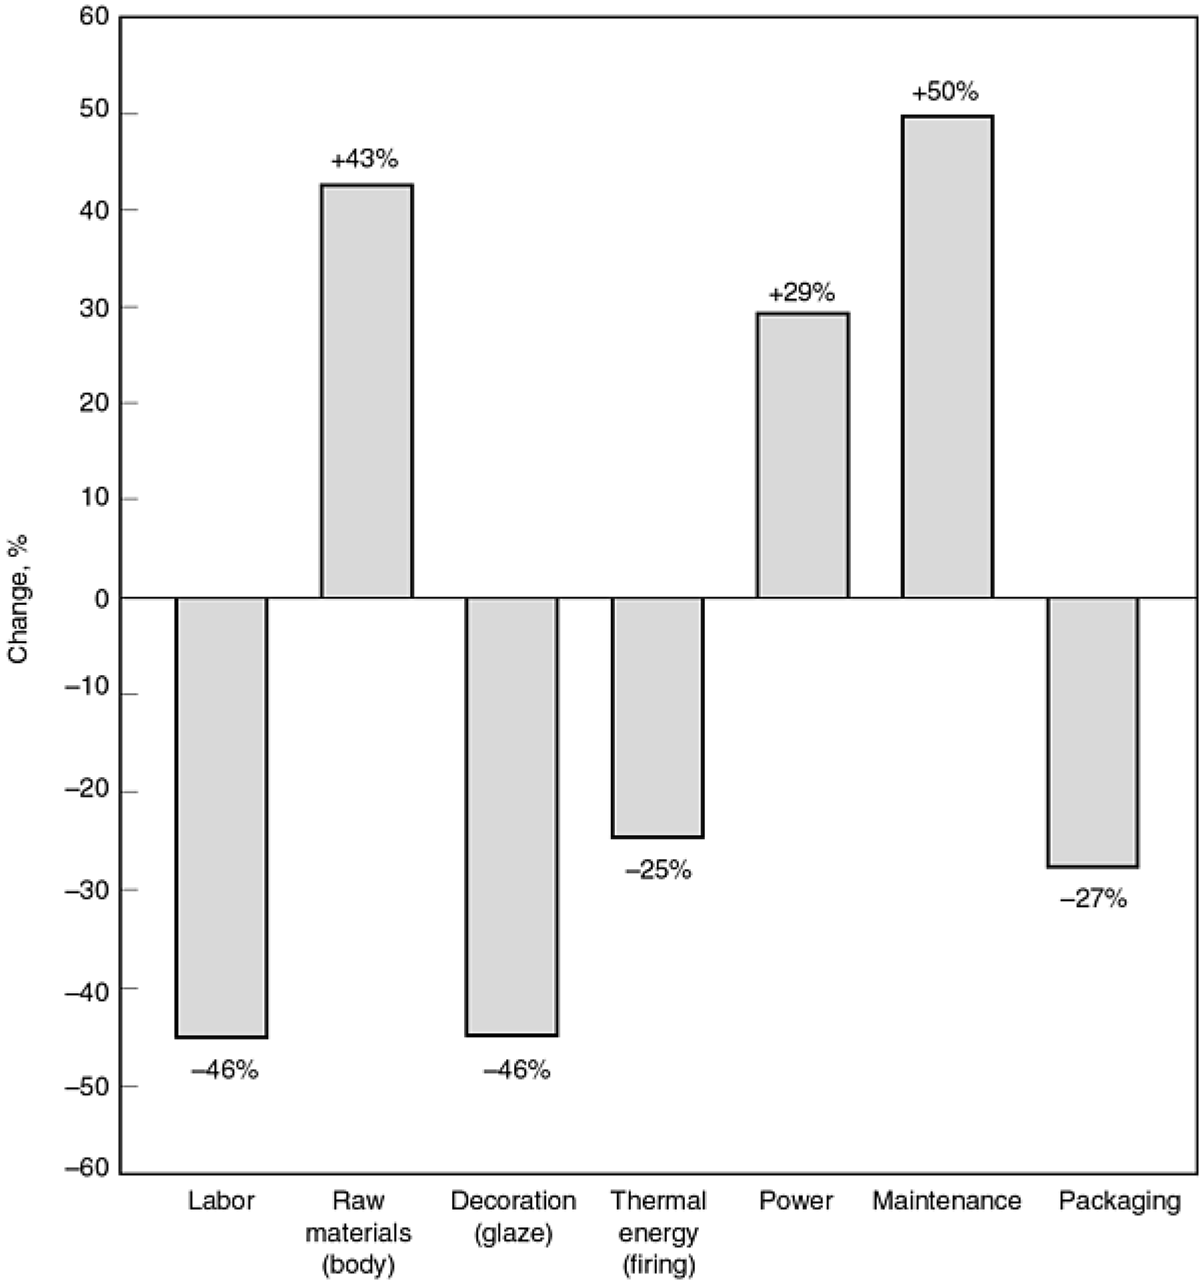

Fig. 4 Relative change in tile productions cost factors (1989 relative to 1971). Source: Ref 1, 2, 3

It may be noted that the cost of labor is a major factor across the two-decade span, but with automation the productivity per employee nearly tripled and employee cost per square meter of tile decreased by about 35%. There was a shift to a more highly trained labor force providing greater turnover and product value. Table 1 shows that tile manufacture is intermediate among major ceramic products in terms of employee productivity and sales value. In general, products lower in value tend to be manufactured in highly automated plants. The use of high-volume, low-cost production is necessary for profitability in such markets except where specialty shapes or properties provide higher-than-usual value added. Significant advances are being made in the volume and yield of sanitaryware and tableware. Many process steps are becoming more automated; where batch manufacture is still employed concepts such as "just-in-time" manufacturing, inventory control, and plant flow of product are improving productivity and lowering rejects. Technical ceramics vary widely in labor (and other) costs depending on the level of value added in manufacture, applicability of mass production methods, need for high-cost raw materials, and special property or shape requirements. It is therefore virtually impossible to make generalizations about technical and advanced ceramics.

Table 1 Relative productivity and product value for ceramic product categories

Product category	Relative productivity[(a)]	Relative value[(b)]
Bricks	1.05	0.15
Sewer pipe	1.00	1.00
Roofing tile	0.91	1.05
Tile	0.79	1.40
Refractories	0.80	1.50
Sanitaryware	0.81	8.90
Tableware	0.41	20.00
Technical ceramics	0.31	10-10,000

(a) Relative pounds per employee-year, indexed to sewer pipe.

(b) Relative price per pound

Costs of body (Fig. 3 and 4) and glaze materials were influenced by a short-term increase in manufacturing costs and the cost of shipping raw materials in the late 1980s. Assuming constant material costs, the body costs would decrease slightly (about 10%) with lowered plant losses offset partially by a small increase to provide the more consistent body formulation required for automation. The glazing cost decreased more substantially because automation replaced the considerable hand labor that is required for traditional decorating. Loss of glazing material and defect losses decreased substantially. Packaging costs (Fig. 4) were also lower because of the elimination of hand labor. The greater reliance on mechanical systems caused increases in both machine-power consumption and equipment maintenance costs, while automated packaging machines lowered that cost segment.

The change in energy consumption is largely attributable to the incorporation of "fast-firing" technology. Historically, large volumes of material were loaded and heated simultaneously for both drying and firing steps. The newer approach employs a belt or roller mechanism in which a very thin support is used. This significantly reduces the thermal load--in particular the nonproductive heating of kiln furniture. The throughput speed is maximized, and residual heat from the firing cycle is used to dry the tile. A 40 to 60% productive usage of heat energy results as compared to an energy efficiency about half of this in conventional firing. This fast-firing paradigm is being applied increasingly to ceramic production. Even when a batch process cannot be converted to a continuous, automated one, considerable savings can be achieved by reducing the thermal load of support materials and firing as rapidly as possible in an energy-efficient furnace. Many plants established firing profiles designed for the largest ware to be fired. Separate firing of large pieces, which require a slower firing profile, can improve efficiency by permitting optimal firing profiles for each shape and size. It has been found to both decrease fuel costs and increase productivity. The latter factor is quite important in a capital-intensive industry in which the investment return of major production equipment is an important consideration.

Shipping is also an important cost factor, although not included in Fig. 3 and 4. For lower-cost, lower-profit margin-products such as construction materials, shipping costs of both finished product and raw materials can be a major factor. Shipping needs often dictate that the plant be placed close to sources or customers, or where lower-cost shipping methods are available.

Design for Ceramic Processing

Victor A. Greenhut, Rutgers--The State University of New Jersey

Design Approaches

Ceramics are frequently specified by design engineers because of their mechanical strength at high temperature, thermal stability, electrical and thermal insulating properties, hardness, and resistance to harsh chemical environments (durability). Special electrical, magnetic, and optical properties also dictate ceramics for various applications. Structural applications of ceramics that are particularly important are construction materials (brick, pipe, tile, etc.), applications where chemical inertness is required (labware, plant piping, tile, etc.), and structures for use at temperatures above about 500 °C (900 °F). Ceramics might be effective design choices for structures for which metals or plastics may be effective at lower temperatures or in less-aggressive environments.

The specific material to be selected depends on its basic properties. Thus a material may be selected based on the chemistry required to achieve the overall behavior desired. Tables 2 and 3 provide key mechanical and other properties for many important whiteware and technical/advanced ceramics, respectively, employed in structural applications. These tables may form an initial guide to materials selection. The properties described refer to materials fired to near-full density. As fired density decreases (due to shorter firing time or lower soak temperature) a given ceramic will generally show poorer mechanical properties, although well-designed high-porosity materials may show adequate strength and are important for thermal insulation applications. As the amount of lower-softening-point glass increases for a whiteware or sintering additive increases for a particular ceramic, full firing can be accomplished more easily. However, high-temperature strength is usually proportionately lower because of a less thermally resistant glass for whitewares or an increase in the amount of grain-boundary phase (usually glassy material) for technical ceramics. Strength and chemical durability is also usually lowered at ambient temperatures as the additive content and consequent firing temperature are reduced.

Table 2 Properties of ceramics

Material	Crystal structure	Theoretical density, g/cm^3	Knoop or Vickers hardness		Transverse rupture strength		Fracture toughness		Young's modulus		Poisson's ratio	Thermal expansion, $10^{-6}/K$	Thermal conductivity, W/m · K

Oxide materials are usually somewhat less expensive than nonoxide ceramics, as their raw material and production costs are lower. Earthenwares and lower-quality whitewares, made from naturally occurring raw materials, generally have the lowest properties and cost with higher porosity (water absorption). The lowest strength is exhibited by many construction materials for which increased load-bearing mass in a structure compensates for lower relative strength. As the density, continuity, and softening point of the vitreous (glassy) phase increases in such materials, the strength, hot strength, and chemical durability usually increase--as does the cost. These property improvements often involve the use of chemically derived raw materials such as alumina. These materials--used as fine china, porcelain, and electrical porcelain--are at the upper end of whiteware properties. Oxide ceramics made chiefly from chemically derived components occupy the next level of resistance to mechanical, chemical, and thermal stresses. Generally, as the amount of second-phase additive and porosity decreases the properties improve. Nonoxide ceramics are usually even more costly and difficult to process, but provide superior mechanical properties and thermal stability, making them particularly applicable for elevated-temperature mechanical applications. However, caution must be used as many nonoxide ceramics oxidize at sufficiently elevated temperatures in air unless a protective oxide "skin" forms.

A useful approach to material selection in ceramic design is to consider a high-performance technical alumina (aluminum oxide), such as 96% alumina, as a starting material. This type of material usually consists of a high-quality alumina raw material into which is milled a 4% (by weight) additive usually containing oxide combinations of silicon, magnesium, and calcium; water and organics that "burn out" on firing are not considered in this formulation. (Caution must be taken in evaluating "96% alumina" or any other ceramic "designation." This is not a specific designation, and significant differences can exist in composition, microstructure, porosity, and consequent properties from manufacturer to manufacturer and with the particular production process selected. This situation holds for most ceramics, and understanding of or advisement in the basics of ceramic engineering can be vital for critical evaluation of materials selection and design.) This is a technical ceramic formulation with moderate cost used for applications such as electronic substrates, mechanical parts, and high-performance chemical ware. Such a material offers very good mechanical performance in terms of strength, toughness, hardness, and wear resistance as well as good chemical durability, high-temperature stability, and thermal shock resistance. If the properties are nearly satisfactory a higher grade of alumina can be used with lower additive content and a somewhat higher material cost.

For still higher performance at elevated temperature, the material selected would move toward silicon carbide or silicon nitride (hot pressed) at increased cost. Ceramic composite materials reinforced with particulate, fiber/whisker, or continuous fiber offer increased protection against catastrophic failure at elevated temperature, but with increased cost. If greater ambient temperature toughness or wear resistance is required, a transformation (zirconia) toughened alumina or zirconia might be employed, each with greater performance and greater accompanying cost. On the other hand, if 96% alumina exceeds requirements a higher glass content alumina can be used with some material economy. If a significantly lower set of mechanical (or other) properties will satisfy requirements, a clay-based whiteware formulation can be chosen. Technical whitewares such as electrical porcelains offer slightly lower performance, with porcelains, stoneware, earthenware, and structural clay ceramics yielding progressively lower mechanical properties at lower cost. A similar logic can be followed for thermal and durability properties with some consideration of specific behaviors of particular materials.

Empirical Design. Most ceramic design is performed empirically, that is by a trial-and-error approach based on past experience. Some consideration of the loads to be experienced and the properties of the ceramic may be included. If the material fails, a modification is made in material, part design, or the applied forces. This is done iteratively until satisfactory performance is achieved. Mechanics models of the stresses in the object and average of material strength or strength distribution may provide a guideline to material selection and design modification. If a part performs properly, it is often used although it may exceed design requirements. However, consideration should be given to whether a ceramic with reduced properties or a modified design might be more cost effective. This approach has been used quite successfully, particularly when failure of the ceramic device or component does not lead to a catastrophic failure hazard. Many specifications for construction materials rely on this empirical approach; experience shows that brick or tile will perform correctly if conventional formulations are used and a minimum test standard is met. A manufacturer of plates or crucibles will similarly use a new material or modify product shape using empirical testing methods.

Deterministic design employs average properties of a material in a particular condition. This method is often applied to metals because an alloy will show, for a particular heat and working treatment, a rather well-defined yield strength and/or ultimate strength with a standard deviation within a few percent of the mean value. The yield or ultimate strength is divided by a safety factor and is used to provide a satisfactory design in calculated continuum mechanics models such as those provided by finite element analysis (FEA) methods. An additional safety factor preventing catastrophic failure is provided by the ductility of the metal. Deterministic methods can be used for ceramics, but the typically brittle nature of ceramic materials can result in a wide variability in failure strength. The strength of a part is dictated by very small flaws manufactured in and induced during use on the object. A deterministic approach requires a very high safety factor because of the flaw sensitivity of ceramics. Much effort toward improving mechanical performance of ceramic materials centers on the elimination of intrinsic flaws produced in forming and firing and extrinsic (surface) flaws formed by postmachining, mechanical abrasion, or environmental attack.

Probabilistic Design (Weibull Analysis). The most rapidly growing approach to ceramic design is the probabilistic method (see the article "Design with Brittle Materials" in this Volume). It permits a fully quantitative approach, as does deterministic design, but deals with the wide variability of strengths dictated by the distribution of flaws in a brittle ceramic. The method accounts for the wide distribution of strengths in conducting the design protocol. It is often integrated with computer FEA models to allow the effect(s) of materials modification, change in flaw population, and part design to be iterated to a successful design in terms of the stresses calculated by finite element analysis. The finite element net is combined with the known statistical failure behavior (flaw distribution) of the ceramic. This protocol is most frequently based on Weibull statistics (Ref 4), which consider the cumulative probability of failure versus failure stress for each element (usually each sample or part).

A typical Weibull plot constructed on a log-probability scale is shown in Fig. 5(a). This plot considers 20 reaction-bonded silicon nitride samples. (While 20 elements appear adequate for this plot, it would usually be considered a small base for design. A common rule of convenience is to test more than 50 samples.) The plot is constructed by ordering the n strength values and assigning each element a probability equal to its rank (from 1 to n) divided by [n + 1]. This approximation to true probability usually leads to less than 5% relative error and allows for simple treatment of a moderate number of failure samples. The slope of the line in the plot (two lines in Fig. 5a) is termed the "Weibull modulus," m. (This "modulus" should not be confused with other mechanical moduli such as the modulus of elasticity.) A higher slope indicates a narrower distribution of failure stresses, that is, a narrower distribution of flaws or a more fracture-tough (damage-tolerant) material. A mean stress for failure can also be determined from the plot. The desired failure probability, for example, one part per million, is used as a design criterion, and the Weibull probability with strength is used to design to this performance requirement. Changes in selected material (fracture toughness), fabrication (intrinsic flaw distribution), finishing (extrinsic flaw distribution), and part configuration or applied forces (stress distribution), can be treated iteratively to yield a final design in terms of material, production requirements, and part configuration for a

particular set of applied forces and environment. Weibull statistics are discussed in greater detail in the article "Design with Brittle Materials" in this Volume.

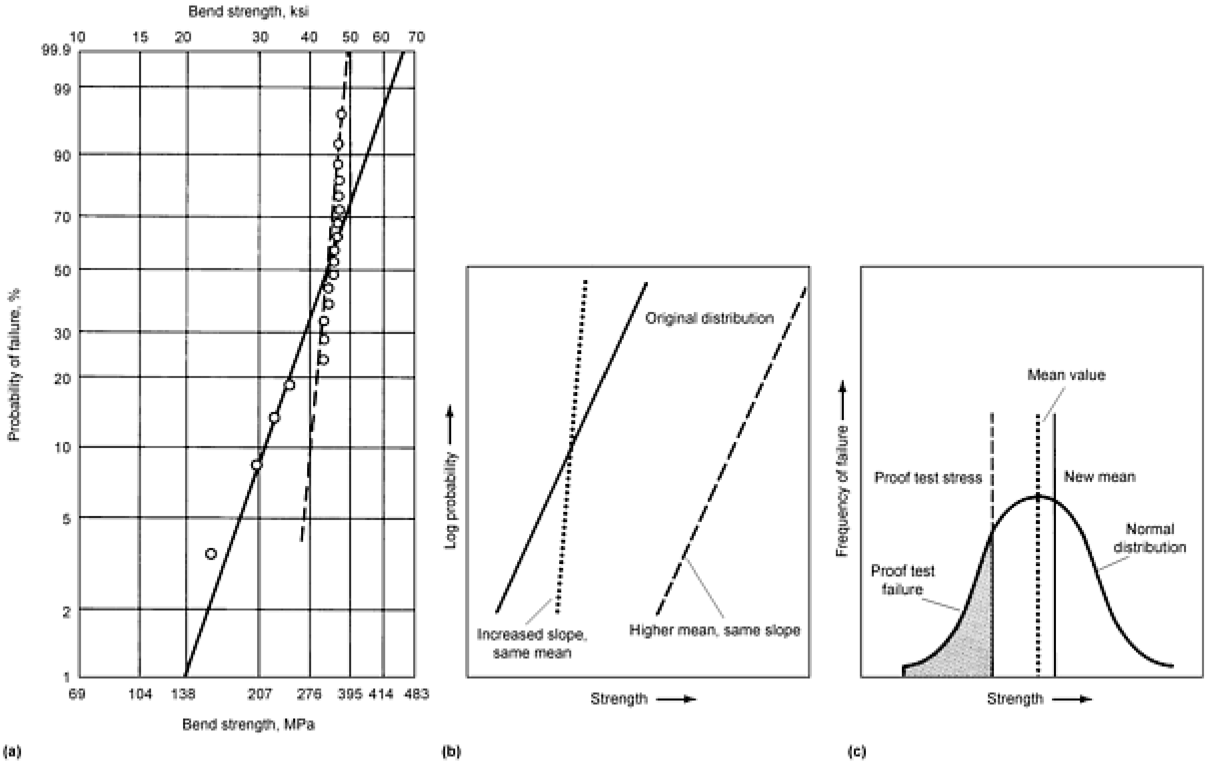

Fig. 5 Statistical aspects of material design. (a) Weibull plot for reaction-bonded silicon nitride. (b) Improved Weibull distributions. (c) Modification of normal distribution by proof testing

The Weibull plot can also be used in several other approaches to improved material or part performance. In Fig. 5(a) two line segments are shown (solid and dashed). The high-strength failures (dashed line) have a higher Weibull modulus (slope) and mean strength than those elements on the solid line, which exhibit greater variability in strength and a lower mean strength. Usually the lower slope and mean indicates a different, more severe flaw for corresponding samples. The overall performance can be improved by examining these severe failure-inducing flaws and/or the specifics of production for the low *m* samples and correcting matters. There are two ways to improve performance by material improvements and/or flaw reduction, as shown in Fig. 5(b). The mean failure value can be increased to yield a higher overall strength, or the Weibull modulus can be increased, improving the reliability by decreasing the distribution of failure values. The improvement in modulus decreases the low-strength portion of the population and allows a higher-use stress at the same failure probability. Some caution should be taken as a high modulus is not necessarily good--severely abraded material may have very low strength but a high modulus because similar large flaws have been introduced throughout all parts. Naturally, a change in material or production method that increases both the slope and mean would be most desirable.

It should be noted that the Weibull modulus approach provides useful tools for improved design of materials and processes. Nondestructive evaluation methods can be used to eliminate samples with large flaws and consequent low strength. If the flaws belong to a separable group of low strength values such that the solid line in Fig. 5(a) can be drawn, the Weibull model can be used unmodified. Another application of this concept is to mechanical proof testing. As diagrammed in Fig. 5(c), all produced parts are subjected to stress at a predetermined proof test level. Parts with large, effective flaws fail (shaded portion) and are eliminated from the population. A new, higher mean value of strength results. There are two cautions:

- If the initial distribution is normal, as shown (one flaw type), normal statistics can no longer be applied.
- If flaws, particularly cracks, propagate during proof testing, the strength and/or Weibull modulus will deteriorate relative to application.

Fortunately, there is significant evidence that little or no deterioration need occur during proof tests if nonimpact types of proof testing in dry environments (prevents chemical attack of flaws) are employed.

Design for Ceramic Processing

Victor A. Greenhut, Rutgers--The State University of New Jersey

General Process Design

Figure 6 shows the overall scheme usually used in ceramic processing. It is a simplified rendering of the steps that are frequently developed by an iterative process involving design, materials, testing (often nondestructive evaluation), and process engineering. Each step and its interaction with others in the process flow stream need to be compatible and optimized to produce a sound, high-quality product. For example, the raw materials selected and their milled particle size strongly affects whether the rheology is appropriate for a plastic-forming process. This in turn dictates drying and firing conditions and the level of defects, density, homogeneity, and anisotropy of the final part. After the overall scheme is introduced, each process area is discussed in overview. An overview of relationships between structure, processing, and properties can be found in the article "Effects of Composition, Processing, and Structure on Properties of Ceramics and Glasses" in this Volume. Detailed presentations of design aspects of ceramic processing can be found in *Ceramics and Glasses,* Volume 4 of the *Engineered Materials Handbook,* and other selected references provided at the end of this article.

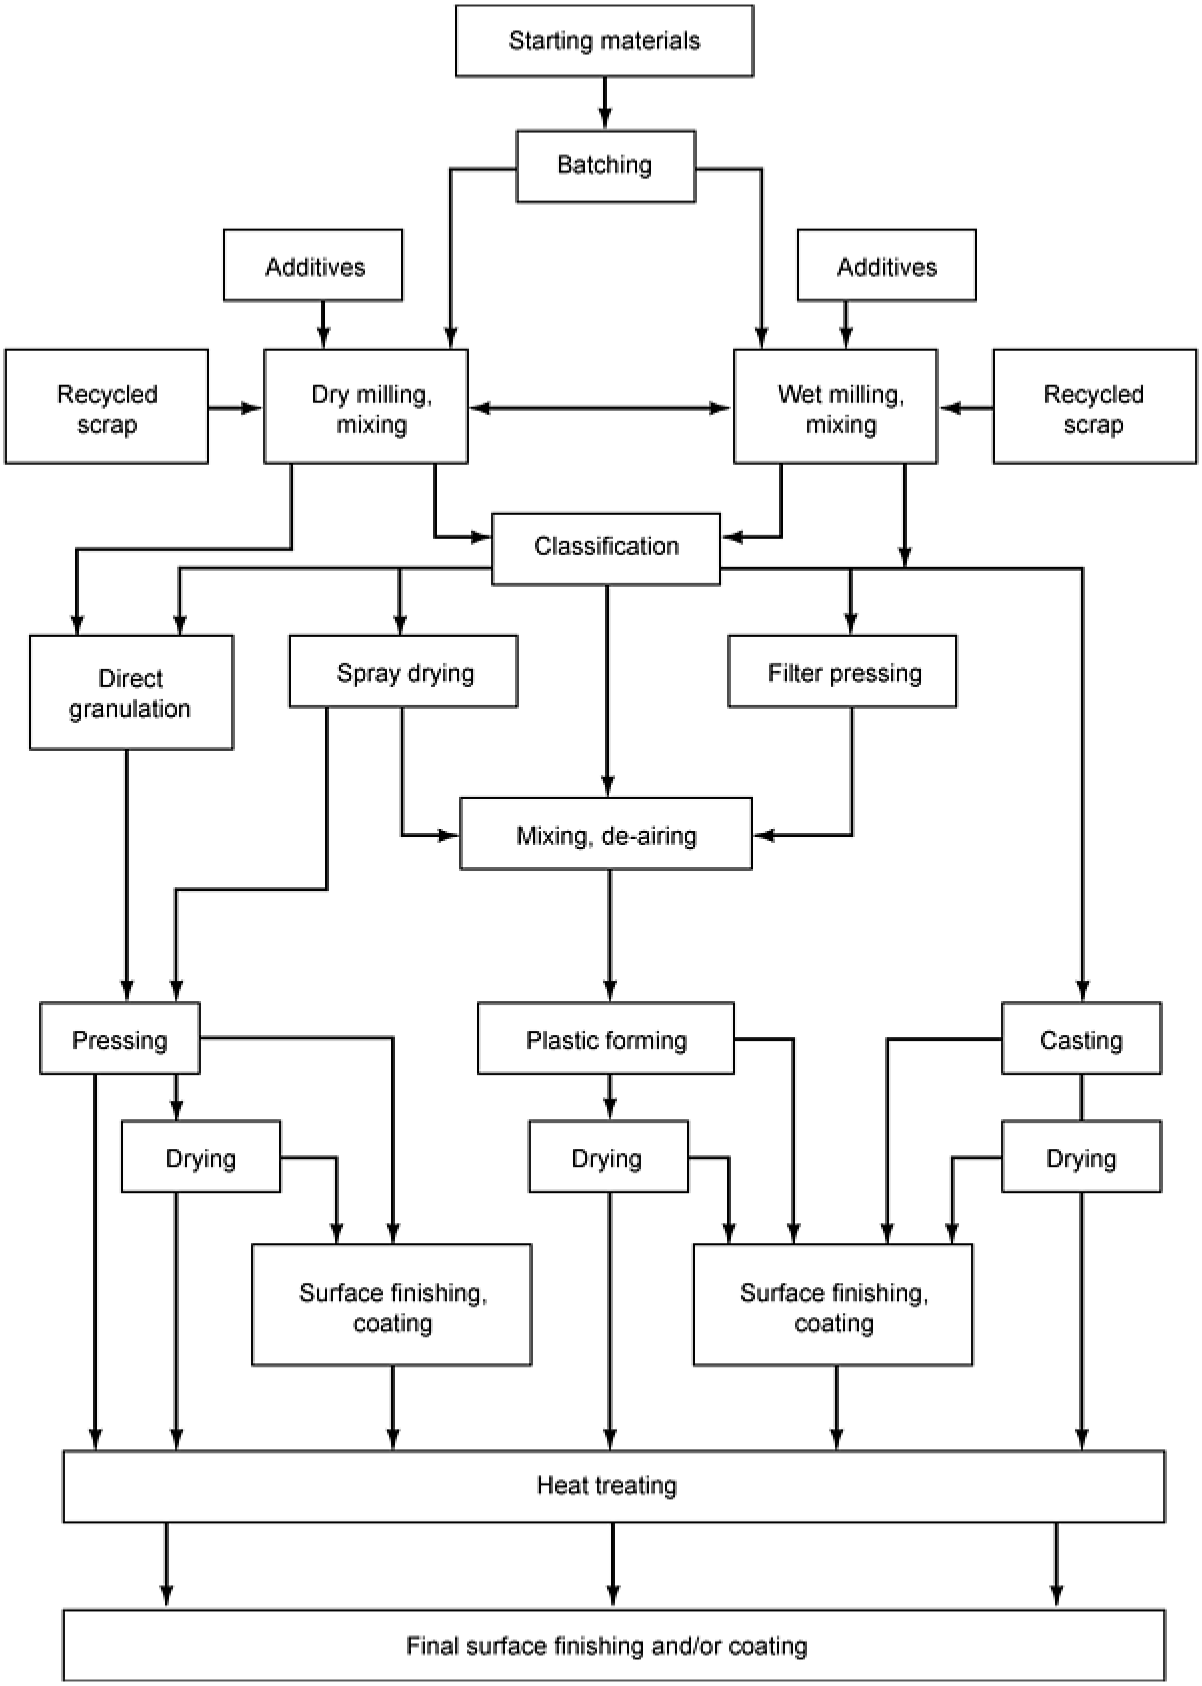

Fig. 6 General ceramic processing flow chart

Figure 6 is divided into various stages. First, the starting materials need to be selected. Subtle, even trace, differences in starting chemistry or structure can alter the mechanical strength, chemical durability, thermal resistance, conductivity, and aesthetics of a ceramic part. For example, a fraction of a percent of additive can substantially alter the high-temperature

strength of a ceramic, decreasing the practical temperature limit of use by many hundreds of degrees. Starting materials are usually powders of natural or derived materials.

The raw materials and appropriate additives are next blended, and particle size distribution adjusted in a milling and mixing step. In blenders, the particles are agitated by either motion of stirrers or of the container. Mills provide particle reduction and break-up of agglomerates by the inclusion of "media" or by other means of applying kinetic energy to the ceramic particles. Various types of mills are available, including ball mills, attrition mills, and jet mills. The powder can then be further prepared for forming by classifying particle sizes and eliminating large particles and agglomerates. The powder can be aggregated by methods such as granulation or spray drying for ease of handling or good forming properties.

The material is then formed by one of three general approaches with decreasing liquid phase (water) content: wet (casting, tape casting), plastic (extrusion, plastic pressing, jiggering, injection molding), or dry (dry pressing, isostatic pressing). The shaped object is then dried. After forming and drying, the part must have sufficient green (unfired) strength for handling and to resist the formation of defects during further processing. The part can then be surface finished by green machining to near final shape (accounting for firing shrinkage), and surface finishes can be applied such as glazes. The part is then fired to the desired density and structure. Final machining to tolerance or postfiring coatings can then be applied. Often, the ceramic may go through a partial process and return to prior process steps. For example, powder can be formed to pellets, fired, and then be reground to become part of a ceramic formulation. Fired parts or partially (bisque) fired parts can be coated with raw glaze and refired. The chart given in Fig. 6 should be viewed as an introductory guide to design processing. It should be recognized that many variations are made in practice on the steps shown.

Victor A. Greenhut, Rutgers--The State University of New Jersey

Ceramic Raw Materials and Formulation

Traditional ceramics are usually made from beneficiated raw materials extracted from the earth and partially purified. As the density, strength, chemical durability, and other properties improve, the raw materials are required to have more controlled composition, greater freedom from foreign matter, and consistent particle size. Traditional ceramics are usually formulated to yield a triaxial body based on the combination of silica, clay, and flux. For some applications, refractory minerals may also be included. A similar concept can be employed for technical oxide ceramics made from chemically derived materials.

The term *triaxial* refers to triaxial phase diagrams based on common mineral raw materials such as those shown in Fig. 7. The corners of the diagram indicate either pure, single metal/oxide materials (Fig. 7a) or minerals (Fig. 7b). In Fig. 7(a) the various phases and stability fields are indicated. A particular composition can be determined by combining raw materials to yield a final result determined by the proportional distances from the "pure" phase vertices. The equilibrium phase diagram shown in Fig. 7(a) is usually used for technical ceramics and pure, chemically processed raw materials would be used. For example, alumina-based ceramics would be produced if the major constituent Al_2O_3, chemically derived from bauxite ore, were combined with minor additions of finely divided quartz (silica, SiO_2) and magnesia (MgO). The complex composition plane of Fig. 7(b) is more useful for whiteware ceramics, which are derived from ceramic raw materials involving more than three oxides. Raw materials and pure minerals are indicated along the sides and vertices, for example, silica, metakaolin (kaolin with its structural water removed), mullite, and feldspar (as leucite or potash feldspar). Regions for various whiteware types are shown inside, for example, hard porcelain, sanitaryware, and electrical porcelain. As with Fig. 7(a), the regions of thermal phase stability are shown. Such diagrams are used to design final ceramic formulations.

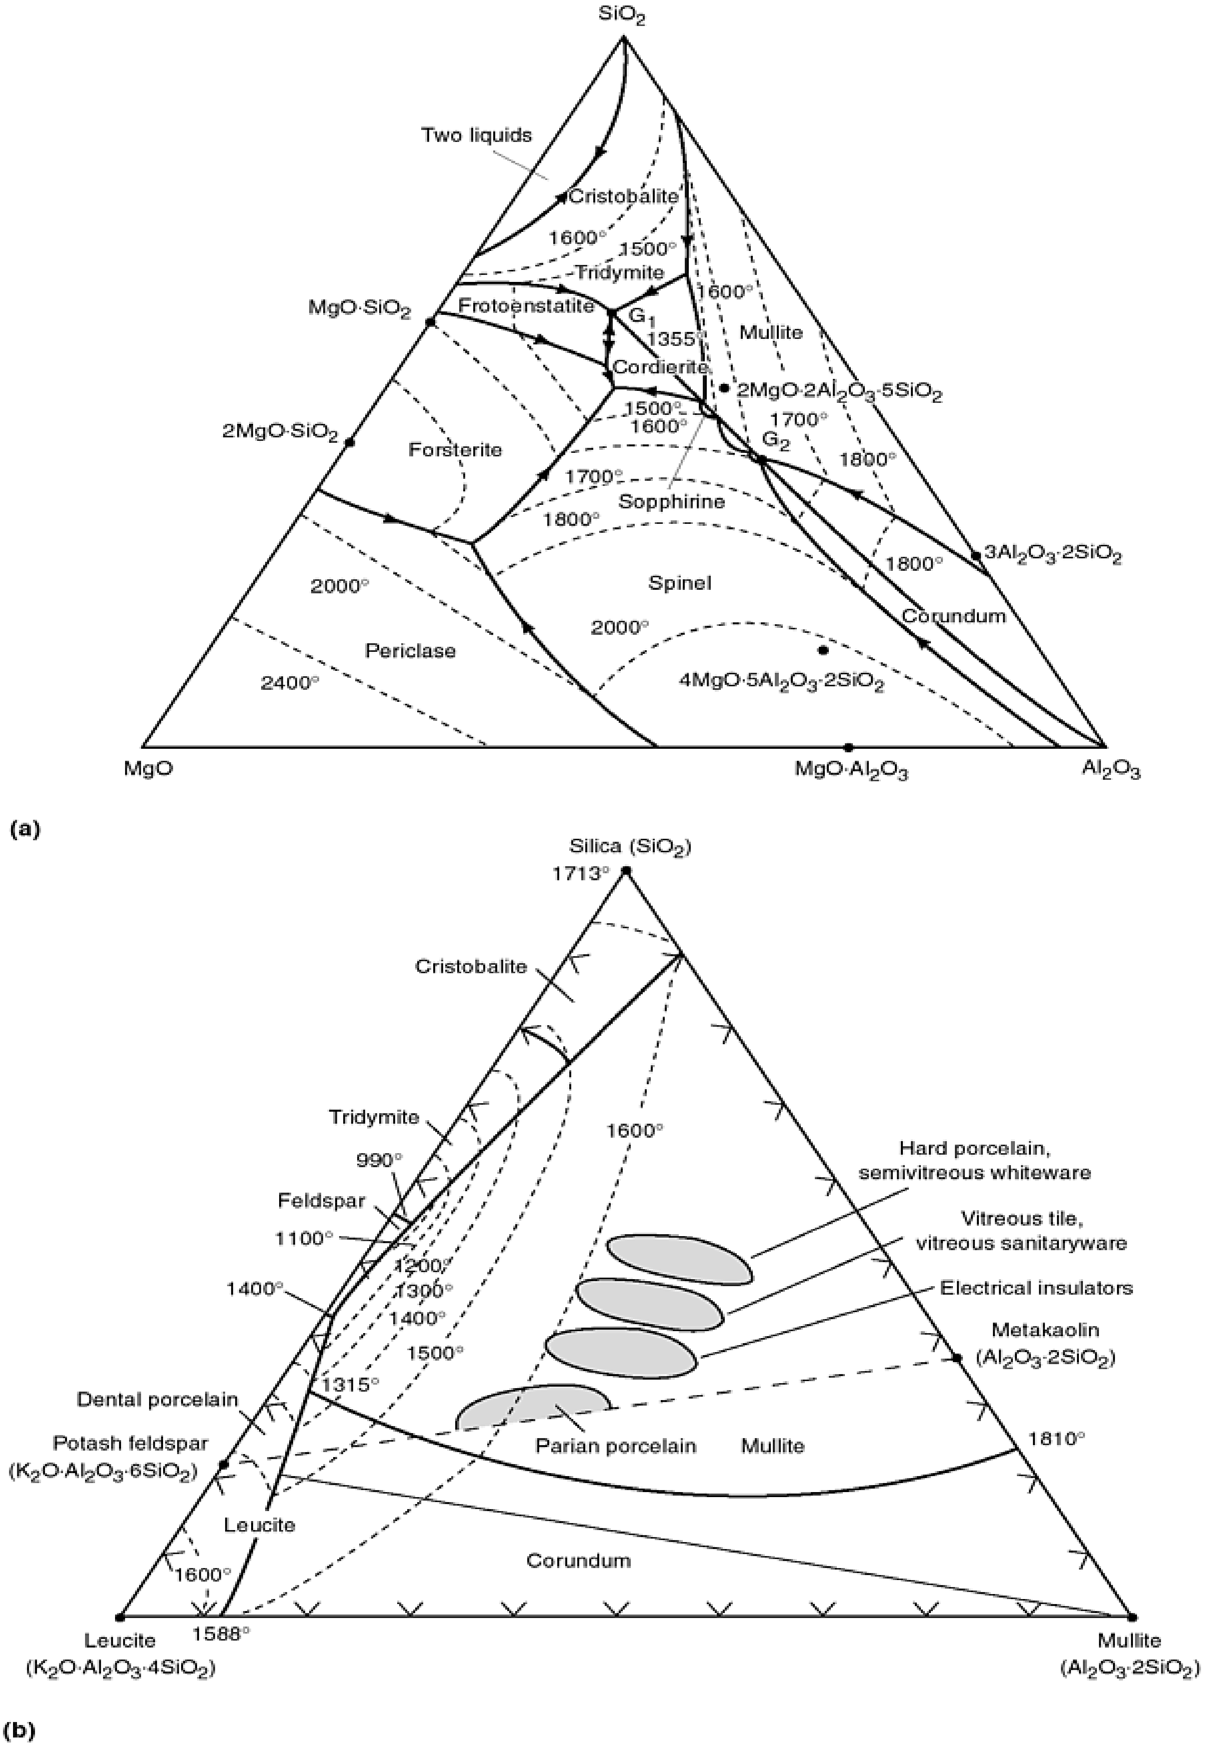

Fig. 7 Ternary phase diagrams for ceramic materials. (a) Diagram of the system $MgO-Al_2O_3-SiO_2$. Dashed lines show isotherms in degrees centigrade for the presence of liquid phase. (b) Areas of triaxial whiteware compositions shown on the silica-leucite-mullite phase-equilibrium diagram

The starting materials may combine several raw materials; for example, alumina may be part of a clay, flux, and refractory oxide, which together supply the total amount of alumina supplied. The actual reaction behavior must be understood because some of the raw material may not react fully during firing. Techniques of batch formulation are used to arrive at the final composition required and involve considerations of organic and water loss as well as cost factors. Sophisticated computer programs have been developed, many company proprietary, to optimize formulation in terms of green forming, firing, final properties, and costs.

Traditional Ceramics. For traditional ceramics, the silica fraction of the triaxial body is usually obtained from rather pure deposits of quartz in the form of beach sand or crushed quartz rock, which is washed, ground, and classified (usually 200 to 400 mesh). A wide variety of clay and mineral materials and hydrated minerals can be used, with kaolin ($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$) and talc ($3MgO \cdot 3SiO_2 \cdot 2H_2O$) being the most common mineral forms. Clays usually provide the plastic fraction of a ceramic formulation when mixed with a small amount of water. China clays, such as kaolinite, are chiefly composed of kaolin and are a principle ingredient of most whiteware ceramics. Ball clays are composed of very fine clay particulate with significant quantities of quartz and organic material. They are particularly useful in traditional ceramic formulations because they provide excellent plasticity and green strength to the body, which are useful for working (shaping) the green ceramic. Fluxes contain alkali, which promotes the fusion of silica, alumina, and aluminosilicates thereby allowing firing at relatively low temperatures. Feldspars and nepheline syenite are common fluxing ingredients. Refractory minerals are usually added for elevated-temperature use when high-temperature strength and chemical resistance are required. A variety of oxides, carbides, and other materials are used.

Advanced ceramics tend to use processed, high-purity, chemically derived powders such as alumina, zirconia, silicon nitride, aluminum nitride, and silicon carbide. Technical ceramics use raw materials both chemically derived and of traditional formulation. As the performance requirements become more critical, chemical purity, controlled particle size (distribution), reactivity, and freedom from agglomeration become more important. The optimal particle size distribution is still a matter of disagreement. An extremely fine, uniform, submicrometer particle size can yield ordered packing, provide freedom from pore defects, provide high sintering or reaction rates, lower sintering time, and prevent exaggerated grain-growth defects. Achieving full density may be difficult because uniform spheres pack with about a third void space. Forming times are long, it is difficult to obtain good forming rheology, and prevention of agglomeration is critical. A broad distribution of particle sizes with many orders of magnitude of particle size down to extremely fine (nanometer) scale will provide denser green packing, and desirable forming rheology is far easier to achieve. Forming time is shortened, although defects (large pores and exaggerated grain growth) require careful control to prevent.

Design for Ceramic Processing

Victor A. Greenhut, Rutgers--The State University of New Jersey

---

Preparation of Materials

The various raw materials are typically ground together to provide intimate mixing and particle size reduction. The configuration, speed, and time duration of milling can significantly alter the intimacy of mixing and ultimate particle size distribution. As milling time increases, the relative improvement in mixedness or particle size reduction decreases in a quasi-logarithmic fashion. Milling is usually done wet with the water or other liquid often being part of the final formulation. In some cases dry milling is done, although many materials are dried after milling.

For slip casting, powders are usually dispersed in water or nonaqueous media resulting in a "slip," a fluid slurry with thixotropic rheology. It is desired to have a material that flows when stirred yet maintains its shape after discharge into a mold. A clear understanding of colloid chemistry and rheological control is vital to proper slip preparation (a similar understanding is important to plastic forming). Factors that affect slip (or plastic working) rheology include: solids fraction, liquid fraction, dispersant(s) type and quantity, particle size distribution, particle surface chemistry, pH, and order (timing) of additions. Both traditional clay ceramics and nonclay technical ceramics can be prepared as slips and plastic masses; however, nonclay materials require greater additive and time control because they have no "natural" plasticity.

Ceramic powders used in plastic forming employ similar additives and liquids to those used in slip casting, but the fluid content is reduced and additive formulation adjusted. A stiff plastic body must be prepared suitable to the particular plastic process, applied stress, and forming rate. Preparation is usually performed in pug mills or sigma blade mixers that

provide high shear. The body must show a suitable yield point (stress at which flow begins) and maintain shape after forming. Bingham viscoelastic behavior (linear relation between shear stress and shear rate with a yield stress) is usually desired. Clay bodies usually can provide the required rheology with minor additives such as dispersants (deflocculants) and through control of clay fractions and particle size distribution. For technical and advanced ceramics that contain no clay fraction organic binders, plasticizers and lubricants are added to obtain appropriate plastic rheology.

Dry pressed powders must usually be granulated or spray dried to provide free-flowing powders that will readily fill a mold. Spray drying usually provides spherical aggregates of powder particles ideal for flow and die filling. Spray drying also permits the uniform incorporation of multiphase materials, binders, lubricants, and other additives. Service firms will spray dry material for those who cannot justify the capital investment of a spray dryer.

Design for Ceramic Processing

Victor A. Greenhut, Rutgers--The State University of New Jersey

Forming Processes

Many forming processes used in ceramics such as dry pressing, extrusion, plastic forming, and injection molding are similar in principle to processes used in the metals, plastics, and food industries. Experience in these areas can be used insofar as rheological behavior is similar. The abrasiveness of ceramics requires that production equipment otherwise similar to other industries be hardfaced to avoid wear and contamination. Slip casting, tape casting, and jiggering are forming methods more specifically developed for ceramic processing. Table 4 summarizes the suitability of various forming processes. The great variability of practices and methods for those described and the number of specialty processes used means that there is significant variation from Table 4, and the descriptions in both Table 4 and this section should be used as a preliminary guide only.

Table 4 Evaluation factors for different ceramic forming methods

Forming methods	Large component sizes	Complex component shape	Independence of plasticity	Tolerance	Ceramic problems (defects)	Production volume	Production speed	Required plant space	Equipment cost
Wet forming									
Slip casting	1	1	3	5	5	5	5	5	1
Pressure casting	2	2	3	4	4	5	4	5	2
Tape casting	3	5[(a)]	4	1	2	1	1	2	4
Plastic forming									
Extrusion	2	3[(b)]	5	3	3	2	2	4	3
Plastic pressing	3	3	4	2	3	2	3	3	2
Jiggering	2	4[(c)]	5	4	4	3	4	3	2
Injection molding	5	5[(d)]	3	1	2	2	2	3	5
Dry forming									
Dry pressing	4	5[(e)]	1	1	1	1	1	3	3
Cold isostatic pressing	3[(f)]	4	1	1	2	4	3	4	4

Note: Under usual circumstances 1 is best, and 5 is worst. Variability in processing methods may deviate from common factors indicated.

(a) Thin sheets only.

(b) Uniform cross section.

(c) Axially symmetric shapes.

(d) Size limited by binder burnout.

(e) Small to medium size, short aspect ratio.

(f) Some very large shapes made

Wet processing methods include slip casting, pressure casting, and tape casting.

Slip casting provides great flexibility of both part shape and size. The major incremental cost for a new shape is development of a master mold. Multiple-use molds made of plaster and/or porous plastics (more recently) are produced from the master with controlled mold porosity--fine pores provide capillarity, coarse pores a larger liquid reservoir. Slip casting most commonly uses a low viscosity, clay-based ceramic slurry, but can also be used for nonclay ceramics with suitable additives for rheological control. Water is the common liquid vehicle. A layer of the slurry deposits on the mold surface as water is drawn off by the porous nature of the mold wall. Capillary suction continues to draw off water and deposit material from the slurry, building up the thickness of the cast structure. Fine fractions may migrate through the drying cake so that the surface microstructure may differ from the bulk. This difference may be desirable for surface finish or fired densification. However, inappropriate chemical segregation or drying/firing stresses can result if segregation is not controlled. Molds must be conditioned with slip before use and dried between casts to maintain casting behavior. After a number of casts either mold definition is lost or capillaries clog, preventing indefinite mold use. Vacuum suction can be applied to the outside of the mold to speed the capillary effect somewhat. Usually, many similar molds are used in sequence to maintain productivity. As a result, space usage is high, considerable labor is required and cycle times are long, although the molds are low-cost forming equipment with great shape and composition flexibility.

Mold time depends on the liquid content of the slurry and thickness of the cross section cast. The ideal slip maximizes solids content so that there is as little water to draw off as possible. Thick cross sections can take a very long time to produce because a parabolic decrease in casting rate occurs with time. For solid casting, a liquid reservoir must be provided in the mold design to provide additional slurry as water is drawn off and shrinkage occurs. Drain casting is used to provide a hollow internal cavity for shapes such as a vase or bowl. After the cake has built up to a controlled thickness the residual slurry is poured off and reused. For all shapes, edges and mold seams are trimmed green (unfired) with a knife and smoothed with a wet sponge. Shapes such as handles can be attached by applying a small amount of slurry to cast pieces and pressing pieces together until attached.

Pressure casting can be used to accelerate the casting speed of thick-walled or solid pieces. Gas pressure injects the slurry into the mold and helps to force the liquid through the mold capillaries. The pressure also allows a slightly lower fluid content in the slip. The pressure also causes an intimate conformance with the mold wall to provide superior definition and surface quality. If yet greater precision and definition is desired, fine particulate can be sprayed on a solid mold made of wax or plastic. This is done in layers with alternate furnace bakeouts and eventual buildup with coarser particulate slurry. Finally the mold is dissolved or burned out. The final product is used as a refractory mold for precision metal casting (investment casting, lost-wax casting).

Tape casting is used to produce thin sheets about 0.1 to 2 mm (4 to 100 mils) thick of ceramic, particularly for electronic substrates and multilayer capacitors. A volatile organic liquid is usually used with appropriate binders and plasticizers that provide rheological control, green strength, and flexibility to the tape produced. The material is drawn across a thin sheet of flexible, nonporous plastic using a doctor blade to control thickness. The continuous ribbon of slurry on plastic passes through a drying oven to evaporate the vehicle. The resulting green ceramic can be cut into pieces and fired after removal from the tape. It can also be metallized, stacked, and punched to produce multilayer capacitors and electronic substrates. Very fine particle sizes, usually of nonclay materials such as high alumina, titanates, and aluminum nitride are usual materials produced in this way. Fine particle size increases strength and permits a thinner tape to be produced.

Plastic Forming. The plastic nature of a clay-based composition makes possible the mechanical shaping of the mass by plastic forming. This has developed from the artisan's hand and potter's wheel shaping of moist clay into processes that allow the mass production of many identical objects. Nonclay ceramics are brought to a sufficiently plastic state by the addition of organic plasticizers. Jiggering represents an automated development of the potter's wheel. The plastic mass is pressed into a die (usually plaster to increase yield of the mass after forming) and formed on the reverse side with a jiggering tool that is a template of the shape desired. Only axially symmetric cross sections can be made, such as dinner plates or oval platters. In plastic pressing the material is pressed by dies in order to form the object. This can be automated to quite high speeds, especially for small, simple-shaped objects. The die can be made of metal or plaster. Plaster is used in order to partially dewater the plastic mass, thereby increasing its yield point (shape retention) at the expense of more rapid tool wear.

Extrusion rapidly forms a uniform cross section, such as for circular or square pipe or thermocouple tubes, by forcing the material out of a die aperture of appropriate shape using a ram or screw auger. The feed angles of the die must be appropriate to provide sound and efficient flow of the plastic mass, but this depends on the rheology of the ceramic at operating temperature and the extrusion rate. If the die angle is improper either inefficient production or defects such as central burst and surface cracks can occur. Aside from the use of abrasion-resistant linings, equipment is virtually identical to that used in plastic and food extrusion. A large cross section such as a large, high-tension insulator blank may be postmachined green to provide contours and varied external or internal diameters.

Injection Molding. Complex objects can be made to precise, near-net shape (accounting for firing shrinkage) using injection molding. A ram or screw feed forces the plastic mass into a mold. The process is similar to that used to form high-volume parts of engineering plastics. This method is not much used for clay-based ceramics because of equipment cost, the need for very high volume production, and the existence of many cost-effective alternate methods. Injection molding has been used particularly for making precise, complex, advanced ceramic shapes, such as turbocharger rotors, by incorporating materials such as silicon nitride into an organic plastic and solvent. Subsequent to forming the binder, material must be burnt out before sintering. This limits the object size to relatively thin cross sections. Work has been done to minimize the amount of binder and to design binders that will burn out rapidly. New water-based systems are being developed that may lower production costs and decrease binder content, burnout cost, and environmental impact of nonaqueous solvents.

Dry Processing. A nearly dry, free-flowing powder (usually spray dried) fills a metal mold and is compacted uniaxially in the process of dry pressing. This method is most suitable for high-volume production of small, simple, low-aspect-ratio shapes with fairly uniform cross section. Die and interparticle friction preclude forming large, long, and complex objects. Internal (in the ceramic) and external (on the die) lubricants are used to decrease friction, thereby facilitating forming and reducing density variations. Multisegment dies, multidirectional pressing, floating die cavities, and high time/pressure cycles can reduce pressure gradients and increase the flexibility of size and shape with high capital costs and part cycle times.

For minimization of density variations and production of more complex (or larger) shapes, isostatic pressing is used. This is often termed cold isostatic pressing (or CIPing) to distinguish it from hot isostatic pressing, a firing process. The nominally dry powder with internal lubricants is filled into a rubbery mold with the desired shape features. The mold is sealed and placed into a hydraulic fluid, which is then pressurized. A part is produced with very uniform density because of the multidirectional pressure and because significantly higher pressure can be achieved compared to that obtained by uniaxial pressing.

Machining. Whenever possible, it is desirable to machine a ceramic while it is still green (unfired). Conventional machining methods can be used and the piece may be machined either before or after drying depending on the strength, shape, and integrity of the part. In some cases, parts can be bisque (partially) fired to provide enough strength for the machining operation while avoiding firing a fully matured piece. Green and bisque firing may not provide critical tolerances, although careful control of both the machining and firing shrinkage may prove adequate. Machining after firing is quite costly (as much as 80% of total cost) and can introduce critical strength-limiting flaws in the material. Postfire machining usually requires diamond tools and slow material removal. New approaches are being developed to increase the machining speed and reduce the damage, thereby improving machining costs and productivity. One successful approach involves very stiff, very-high-speed, multiple-head, multiple-axis machines that are quite capital intensive.

Drying

Drying involves the removal of free, nonstructural water or other solvents from a formed ceramic. It is a two-step process controlled both by internal flow of liquid to the surface and surface evaporation of the liquid. The internal flow can be increased by increasing permeability with a coarser structure, decreasing the viscosity of the liquid or increasing the concentration gradient to the surface (more rapid removal of surface liquid). Evaporation can be hastened by air motion

(removal of saturated vapor), increased temperature, lower vapor pressure liquid, increased drying surface area, decreased air humidity, or reduced pressure.

Drying occurs in three stages, as shown in Fig. 8. At high moisture content, liquid is the continuous phase both in bulk and on the surface and evaporates almost as if it were free, continuous liquid. This is the constant rate period, region A of Fig. 8. In this region, evaporation dominates the drying rate. Most drying shrinkage occurs during this stage. An excessive drying rate can cause differential shrinkage in thick cross sections. Warping or cracking may result, dependent on whether the body can accommodate the drying stresses or not. When the surface film of liquid becomes discontinuous, the first falling-rate period with a linear drying rate begins, region B. Liquid is still continuous in the ceramic as large pores are being drained. There is a small amount of shrinkage in this region, so that the transition from the constant rate to the first falling-rate period is often considered the critical liquid content for shrinkage damage. However, some care must also be taken not to dry too rapidly in the first falling-rate period. In the second falling-rate period, region C, the drying rate is nonlinear. Air is the continuous phase, and liquid pockets are removed by evaporation. If liquid is distributed uniformly in the body, there is no shrinkage in the second falling-rate period. Additional causes of damage due to differential shrinkage are: mechanical restraint of the body, preferred particle orientation, uneven drying, and varying cross sections of the body.

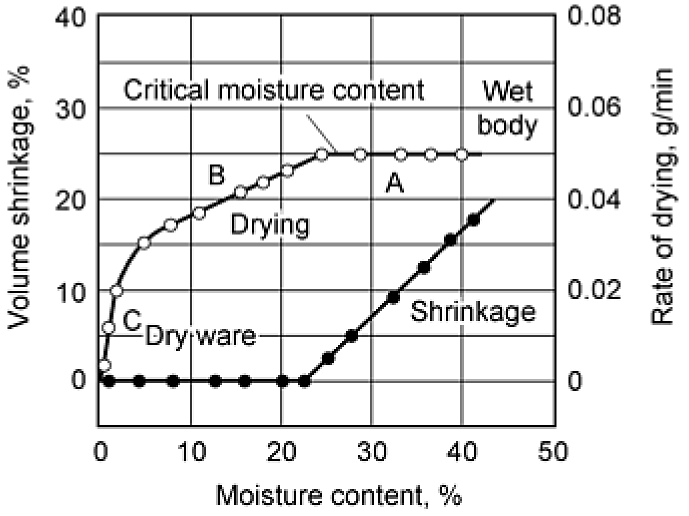

Fig. 8 Change in bulk volume on drying a ceramic body

Drying can be performed as a separate or integrated operation with firing. A drying oven or heat lamps can be used to remove liquid. There has been some success with industrial microwave drying, because of the ability to heat the object more uniformly in depth and thereby both speed up liquid removal and avoid drying stresses. Another trend is to reduce the mass or load and fast-dry parts, thereby increasing throughput and lowering fuel costs. The use of firing-waste heat for drying can also lead to cost reduction.

Firing

When a dry, green ceramic is exposed to elevated temperature, chemical and physical changes occur that consolidate the material, cause an irreversible shrinkage and increase strength and other properties. Vitrification and sintering are the two processes that generally pertain to ceramic firing.

Vitrification. Traditional clay-containing ceramics and other systems that are based on triaxial body formulations most commonly vitrify. Constituent materials react at elevated temperature to form a large amount of liquid phase. This liquid consolidates the body through capillary forces. Most of the liquid forms a continuous glassy phase upon cooling. Figure 9

shows a typical firing curve for a whiteware ceramic. The heating rates and temperature holds are dictated by the transformations that occur during heating and cooling. The correct amount and composition of viscous glass is needed to mature the part at an optimal rate and energy cost while preventing it from slumping and flowing. Usually, a support structure is used to prevent excessive deformation, and some slumping may be precalculated to bring the object to its desired final shape during firing.

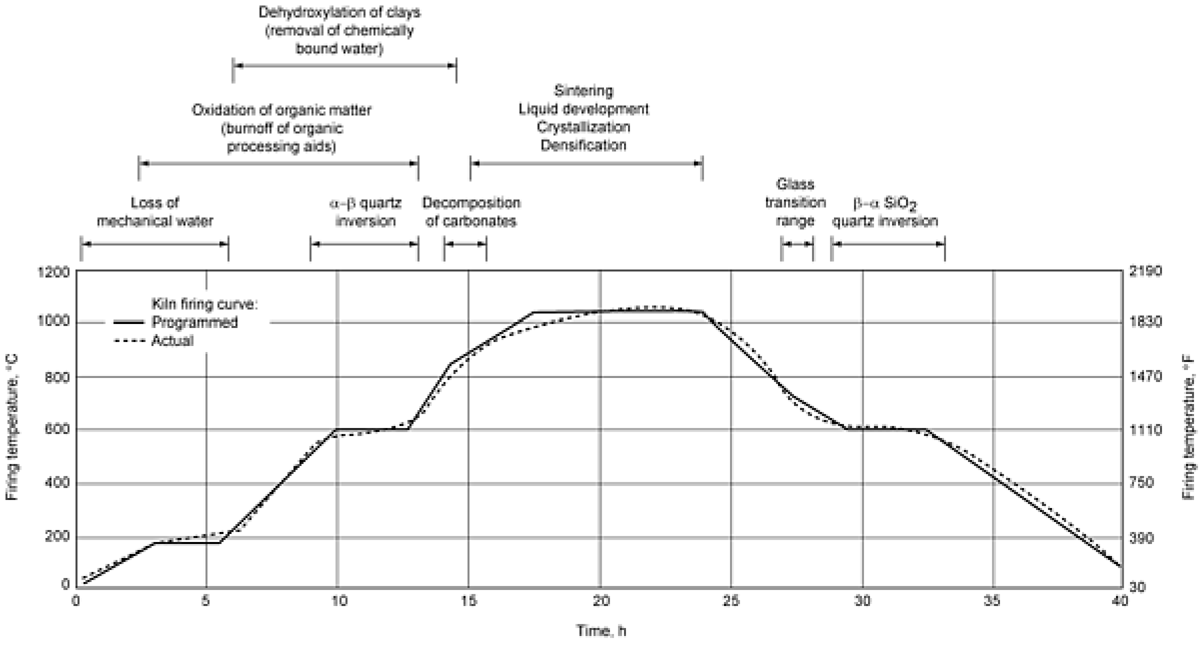

Fig. 9 Typical firing curves with corresponding reactions obtained for clay-bearing ceramic compositions

Some of the glassy material may crystallize on cooling, forming microstructural constituents that depend on liquid chemistry and cooling rate. During cooling, crystal phase changes that will create internal cracks must be avoided. In addition to the dictates of material change that determine a complex firing profile, the shape of thick or large parts must be considered. The thermal profile of the object can introduce stresses on heating or cooling that will warp or fracture the part. Large, thick-walled, and complex shapes must be fired more slowly to prevent damage. Economies can be obtained by separating by size to optimize firing speed and minimize damage. Several manufacturers have developed computer algorithms to predict optimal firing curves for both traditional and advanced ceramics.

Sintering. Ceramics that do not produce a great deal of glassy phase during firing mature by the process of sintering. This is the densification by solid-state diffusion at elevated temperature driven by reduction of surface area. Several processes or stages can occur including evaporation-condensation and surface and bulk diffusion. Usually a small amount of sintering additive (sintering aid) is introduced to accelerate the sintering process by introducing liquid-phase sintering and/or accelerating diffusion rates. Other additives function as grain-growth inhibitors, preventing the competitive process of crystal growth (large crystals may deteriorate strength and other properties). The liquid phase usually forms a thin glassy layer on the grain (crystal) boundaries of the fired ceramic and has a substantial effect on mechanical, electrical, thermal, and magnetic properties. This grain-boundary film has been identified in virtually all manufactured ceramics--even those with trace amounts of additive or impurities. A careful balance must be struck between pore reduction by densification and grain growth. The sintering additives make ceramics prone to exaggerated grain growth, which may deteriorate properties. It is even possible for large, agglomeration pores to grow during firing. As with traditional ceramics, firing stresses must be controlled. The firing process must be understood and carefully optimized if a proper microstructure and properties are to result.

Firing Process Factors. Peak temperature during the soak period is usually considered the most important factor in either vitrification or sintering because a critical temperature is needed to promote reactions between phases, production of glassy liquid, and activation of transport mechanisms. Time, the precise firing profile, atmosphere, and pressure are also important. All of these factors must be balanced in order to maximize productivity, minimize production costs, and optimize properties. Sufficient time must be provided for appropriate transport, reaction, and densification. Heating and cooling rates must not cause excessive body stresses. Oxidizing or reducing atmospheres may promote the formation of

specific phases, chemistries, or defect structures. For example, a fraction of a percent of oxygen deficiency will change titania and zirconia from white to black, and atmosphere has a critical effect on high-temperature superconductivity. While most ceramics are fired in conventional furnaces at near-atmospheric pressure, significant mechanical and other property improvement can be accomplished by firing under high pressure. This may be done with a unidirectional hot press in which rams apply pressure in a die or with a hot isostatic press (HIP) in which gas applies pressure to a sealed ceramic at elevated temperature.

Most ceramics are fired in electric or gas kilns using programmable controllers or computers connected to calibrated thermocouples or pyrometers. Pyrometric cones are a convenient means of monitoring the thermal work input to the fired parts. They are tall, triangular pyramids of ceramic of varied composition that soften and slump at controlled combinations of temperature and time. A series of such cones can be used to verify that the correct firing conditions have been achieved. In addition to computer control of firing, efficient use of fuel, and use of waste heat for drying, several new trends in firing have improved economy and productivity. Fast firing of a small thermal mass in a continuous process is growing in application. Microwave firing and use of chemical reaction energy to augment other energy input are being used on a small scale and are actively being researched.

Conclusions

Both traditional and technical ceramics are based on powder raw materials that are formed into green (unfired) ceramics, dried, and fired. All process steps are critical for producing a material with superior and reliable strength properties. Generally, the more highly fired material will have lower porosity and improved mechanical performance. The transition from traditional to advanced technical ceramics is a continuum; in general, technical ceramics are made from higher quality, more chemically derived raw materials processed with similar techniques as traditional ceramics, but with stricter control.

Design for Plastics Processing

Edward A. Muccio, Ferris State University

Introduction

DESIGNING A PLASTIC PART that will meet customer application demands and be durable enough to survive years of use requires the product designer to consider several factors, such as:

- Plastic material(s) to be used
- Product shape and features
- Production process
- End-use applications

The relationship among these and other factors that influence the production of quality plastic parts is represented in Fig. 1.

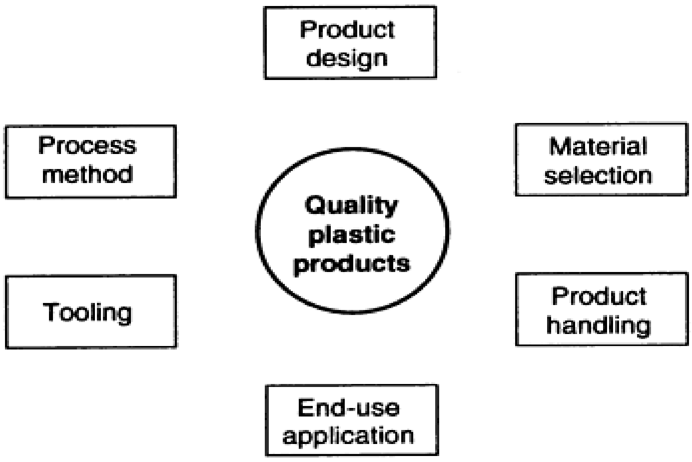

Fig. 1 Key factors in the development and production of quality plastic parts

The product designer must also consider that the plastic molding or forming process influences the plastic part performance. The physical, mechanical, and chemical properties of the material can be affected by the molding/forming process. The part designer needs to understand the rudiments of plastic processing methods in order to select a plastic material, define the specific shape of the part, and define the process used to manufacture the plastic product.

This article describes key processing methods and related design, manufacturing, and application considerations for plastic parts; it concludes with a discussion of a materials selection methodology for plastics. More detailed coverage of the processes discussed in this article, including process considerations for different types of plastics (that is, thermoplastics and thermosets) is provided in *Engineering Plastics,* Volume 2 of the *Engineered Materials Handbook,* and the *Engineered Materials Handbook Desk Edition,* both published by ASM International. Related coverage in this Volume is contained in the articles "Effects of Composition, Processing, and Structure on Properties of Engineering Plastics," "Design with Plastics," and "Design for Composite Manufacture."

Edward A. Muccio, Ferris State University

Plastics Processing Methods

The primary plastics processing methods are:

- Injection molding
- Extrusion
- Thermoforming
- Blow molding
- Rotational molding
- Compression molding/transfer molding
- Composites processing
- Casting

Other plastics processing methods exist, but most are variants of these processes. Table 1 lists characteristics and capacities of processing methods used for thermoplastic and thermoset parts.

Table 1 Thermoplastics and thermoset processing comparison

Plastics processing is a form conversion process. The material that enters the process as plastic pellets or powder is basically the same material that exits the process as a plastic part. The plastic process converts the shape of the plastic material. However, this simple explanation of plastic processing needs to be slightly modified. Although the plastic entering the process is the same plastic exiting the process, the properties of the plastic material may be affected by the rigorous activities that occur during the process. The resulting properties of the plastic part may be different from the properties of the plastic material as defined by the plastic material manufacturer.

Each processing method can have a different effect on the final properties. Following is a brief description of the primary plastic processing methods and a summary of how each process influences part design and the properties of the plastic part.

Injection Molding

Injection molding, and all its variants, is the most popular process for producing plastic products. Designers prefer the injection molding process because, in addition to being fast and cost effective, it allows the designer the opportunity to create true three-dimensional part shapes. (Many plastic processes, such as extrusion, blow molding, thermoforming, and rotational molding, do not allow the designer to control all surfaces of the plastic part being manufactured. One surface is a function of the process, not the product design; some examples include the inside of a hollow container produced by blow or rotational molding, the length of an extruded profile, and the outer surface of a thermoformed part produced on a female mold.)

Product designers desire control over all aspects of the design of a product, and injection molding allows this to occur. Additionally, injection molding allows the designer to incorporate product design features such as holes, snaps, color, texture, and symbolization that might demand secondary operations if the design were manufactured using materials such as metal, wood, or ceramic.

The injection molding process involves several steps:

- Feed and melting of the plastic pellets
- Metering of the plastic melt
- Injection of the plastic melt into the mold
- Cooling and solidifying of the plastic in the mold
- Ejection or removal of the molded part from the mold

The following description of these steps is based on the processing required to mold a simple part such as the polystyrene poker chip shown in Fig. 2.

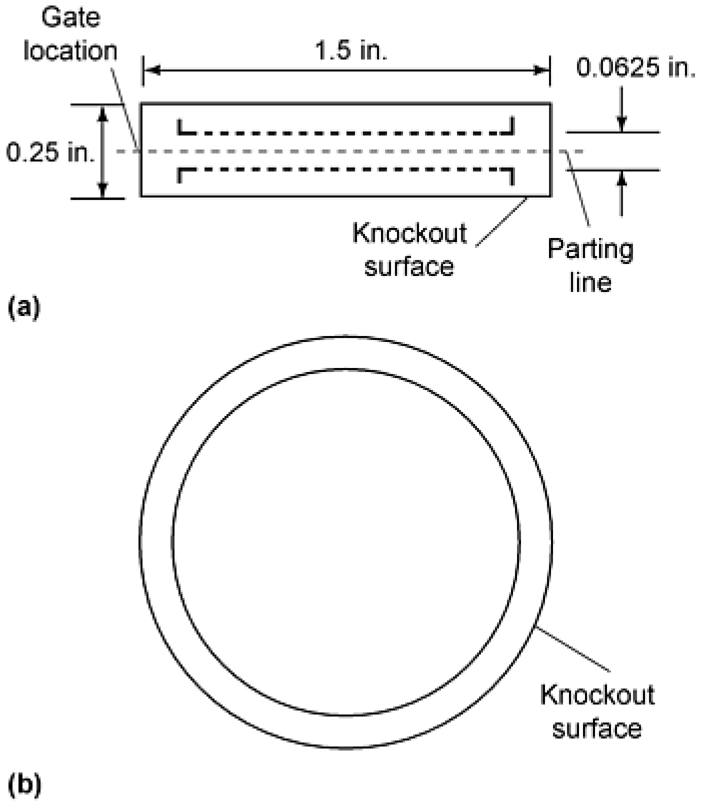

Fig. 2 Polystyrene poker chip. (a) Side view. (b) Bottom view

Feed and Melting of the Plastic Pellets. The polystyrene, in the form of pellets, is fed into the throat of the injection molding machine (Fig. 3). Initially, the plastic pellets are heated by the electric heater bands; however, the shear and friction created by turning the injection molding machine screw will provide the majority of the energy required to melt the plastic.

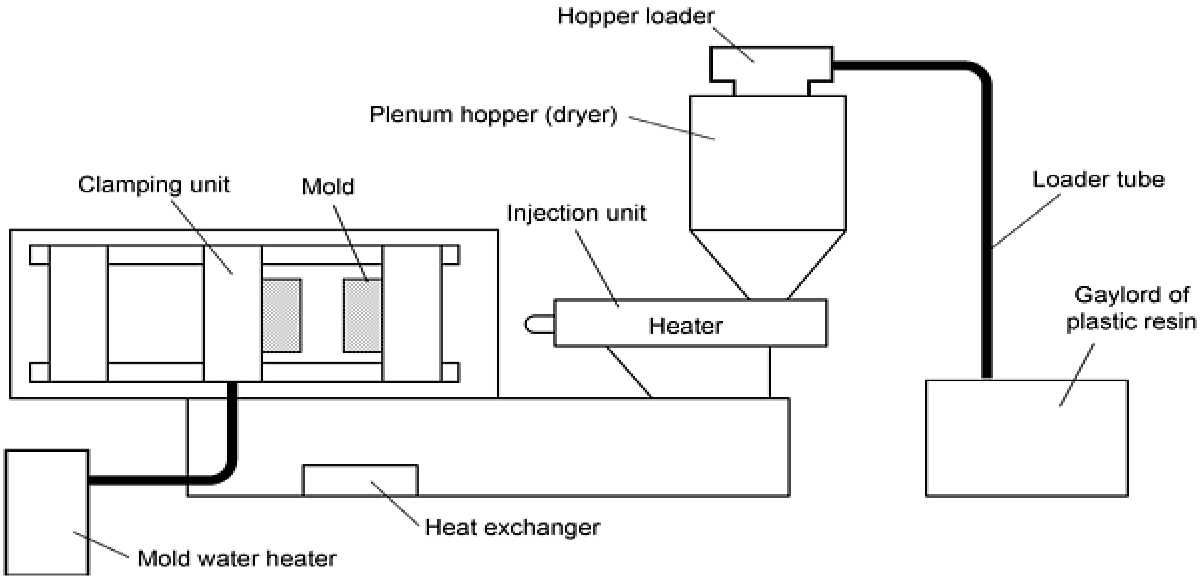

Fig. 3 Injection molding machine

As the screw turns, the plastic pellets melt, and the melted material is conveyed toward the discharge end of the injection unit.

Metering of the Plastic Melt. As the plastic melt is conveyed forward through the barrel of the molding machine, it is allowed to pass through a nonreturn valve that prevents the plastic melt from traveling rearward or back through the valve. The plastic melt that moves through the valve and in front of the screw will push the screw rearward. This rearward motion of the screw, while the screw is turning, creates more shear and facilitates the melting of the plastic pellets. The amount of plastic melt that is allowed to move through the valve and reside in front of the screw is defined by a limit switch or stopping point assigned by the molding technician. The plastic melt in front of the screw will be the material that is injected into the mold to produce the plastic parts.

Injection of the Plastic Melt into the Mold. Injecting the plastic melt into the closed mold requires high pressures (between 35 and 205 MPa, or 5 and 30 ksi, on the plastic material) and often high speeds. The specific values for injecting the plastic melt are a function of the melt viscosity of the plastic material, the mold design, and the plastic product design. To allow the injection of plastic into the mold, the part designer must consider design features such as the wall thickness and gate type and location.

Wall thickness, the thickness of the major portion of the wall of the plastic part, depends on the melt characteristics (melt viscosity) of the plastic. A plastic part with thin walls (<1 mm, or 0.04 in., thick) will usually require higher molding pressures than a plastic part with a wall thickness of about 4 mm (0.16 in.). Thicker wall sections (>6 mm, or 0.25 in., thick) may result in poor part quality and molding defects such as underfill or sink marks.

Gate Type and Location. The gate (Fig. 4) is the point where the plastic melt is allowed to enter the cavity to form the part. The gate is designed to cool or freeze after the cavity has been filled and packed with plastic. This cooling prevents any plastic melt from exiting the filled cavity.

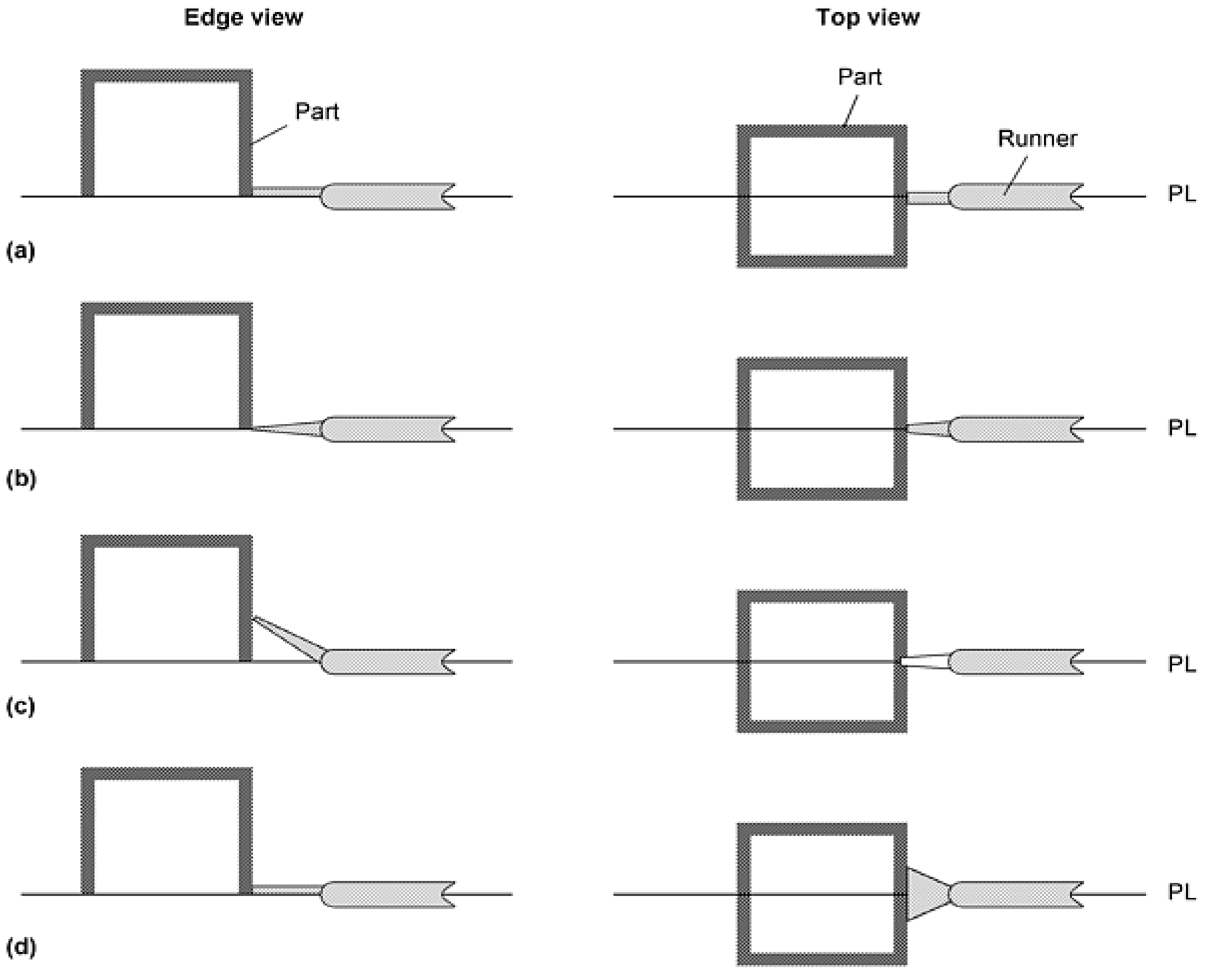

Fig. 4 Types of injection molding gates. (a) Tab gate. (b) Pinpoint gate. (c) Sub gate. (d) Fan gate. PL, parting

line

Cooling and Solidifying of the Plastic in the Mold. Plastic materials are thermal insulators; that is, they tend *not* to absorb or release thermal energy at a rapid rate. The plastic part designer must avoid thick wall sections to avoid cooling problems in the mold. Specifically, parts with thicker wall sections require a longer cooling time within the mold; additionally, the thick sections may distort, have sink marks, or contain voids (Fig. 5).

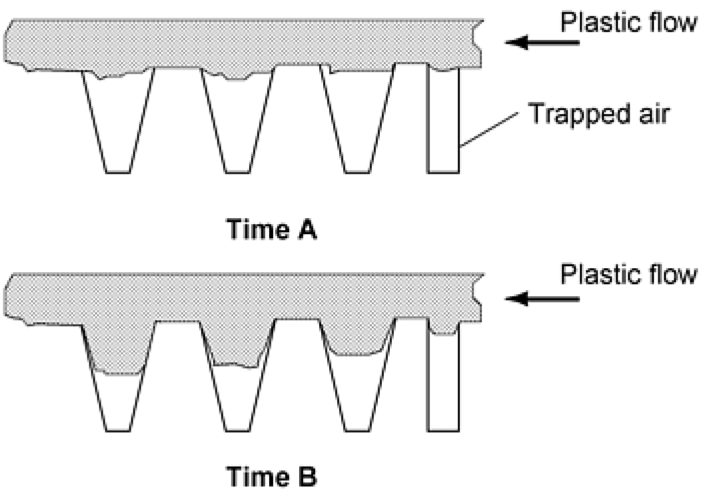

Fig. 5 Problems in cooling and solidification caused by the rib fill rate for an injection-molded part

To avoid these problems, the designer must strive for a nearly constant thickness of every section of the part. This *nominal* thickness must meet the application requirements of the part, ensure nearly uniform cooling, and be fillable by the plastic material selected. As an example, a plastic material manufacturer may suggest a nominal wall thickness of 4.5 mm (0.18 in.) for a specific plastic. The plastic part designer is not bound to make all the walls this thickness, but should design the wall to average this dimension. The wall thickness may vary, but only at a reasonable rate of change (Fig. 6).

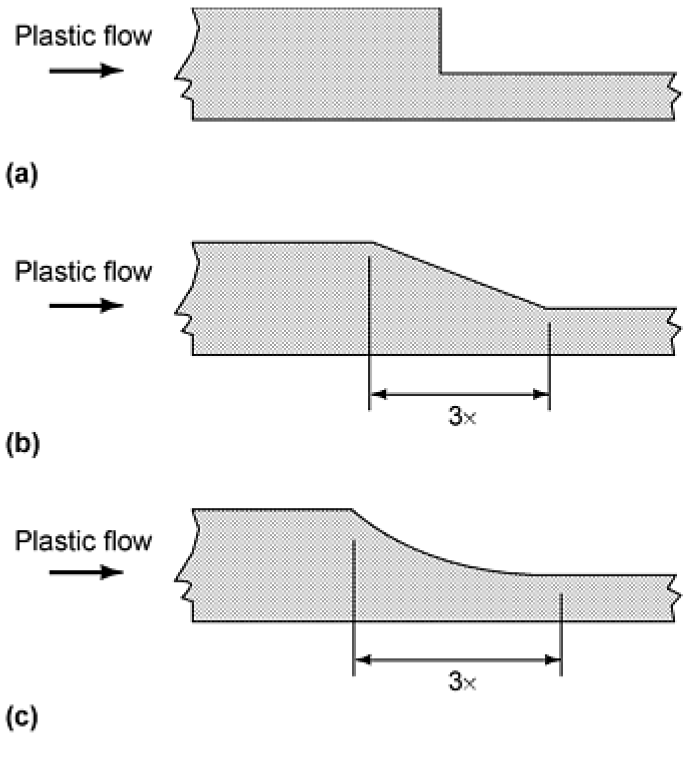

Fig. 6 Wall transitions in a plastic part. (a) Poor (sharp) transition. (b) Better (gradual) transition. (c) Best (smooth) transition

Ejection or Removal of the Molded Part from the Mold. To allow an injection-molded part to be removed from the mold requires that the part designer consider ejection surfaces and draft.

Ejection surfaces on the part provide an allowance for ejector pins to push the part out of the mold (Fig. 2). The ejector pins or other mold components such as inserts and slides will leave a witness mark on the plastic part, which the plastic part designer needs to respect. Often the part specification will include a note that states "knockout witness to be flush to or 0.125 mm (0.005 in.) below the molding surface."

Draft is the angle in the wall design that facilitates ejection from the mold (Fig. 7).

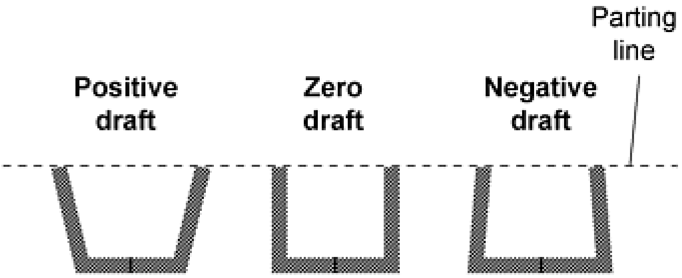

Fig. 7 Types of draft in plastic injection-molded parts

Details and design considerations for injection molding include shrinkage, postmold shrinkage, and size and location of holes and other features.

Shrinkage occurs because the plastic melt volume is greater than the solid volume, and the plastic melt is packed into the mold under high pressures. Shrinkage needs to be understood in order to produce plastic parts with a high degree of dimensional stability. Different plastics experience different amounts of shrinkage (Table 2). Additives affect the shrinkage rate. Rate and direction of flow of the melt into the mold can influence shrinkage and may cause the same material to exhibit two different types of shrinkage depending on the part geometry.

Table 2 Shrinkage of selected plastic materials

Material	Shrinkage, %
Amorphous plastics	
Acrylic	0.6
Polycarbonate	0.6
Acrylonitrile-butadiene-styrene (ABS)	0.6
Polycarbonate (40% glass filled)	0.3[(a)] 0.5[(b)]
Semicrystalline plastics	
Polyethylene	2.0
Polypropylene	2.0
Nylon 6/6	1.5
Nylon (40% glass filled)	0.8[(a)] 0.3[(b)]

(a) Flow direction.

(b) Transverse direction

Postmold Shrinkage. It is best to have any shrinkage occur while the plastic part is constrained by the mold. Shrinkage that occurs outside the confines of the mold after the part is ejected, known as postmold shrinkage, may be uncontrolled and/or unpredictable. The result could be a major dimensional problem for an injection-molded part. Postmold shrinkage is a function of both the plastic material and the process. Several semicrystalline plastics tend to exhibit a higher potential for postmold shrinkage.

If the injection molding process is not optimized, it can contribute to postmold shrinkage. For example, consider an injection molding process that has the plastic melt in the barrel at 260 °C (500 °F) and a mold temperature of 82 °C (180 °F). The desire for productivity gains, that is, output of more parts per hour, leads to cooling the mold to 38 °C (100 °F) and speeding up the cycle. The result of this process change may not be immediately visible. While output gains may be achieved, the lower mold temperature may cause a higher degree of molded-in (residual) stress. This increased stress may be relieved after the part is removed from the mold. Over the next hours, days, or weeks, the relieving of the stress may manifest itself as postmold shrinkage.

Holes and Other Features. Injection-molded part features can be expressed as a function of the nominal wall thickness (*T*) as shown in Fig. 8 and 9.

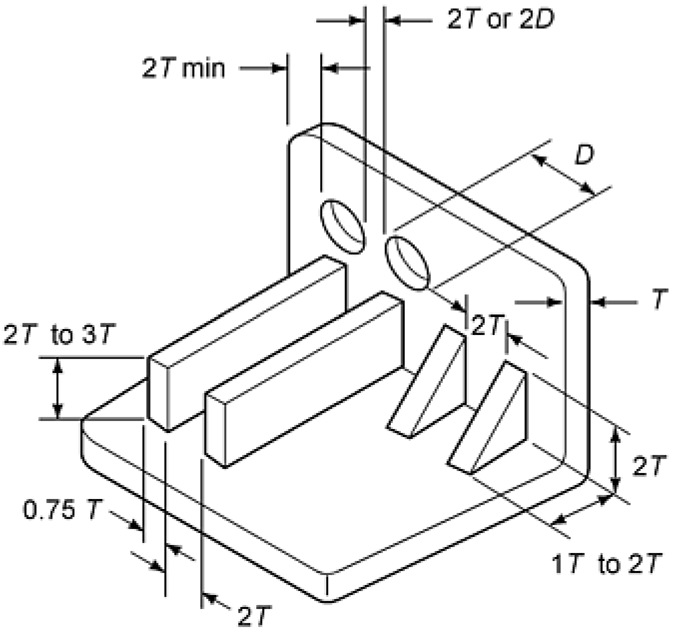

Fig. 8 Good design practice for holes and projections in injection-molded parts

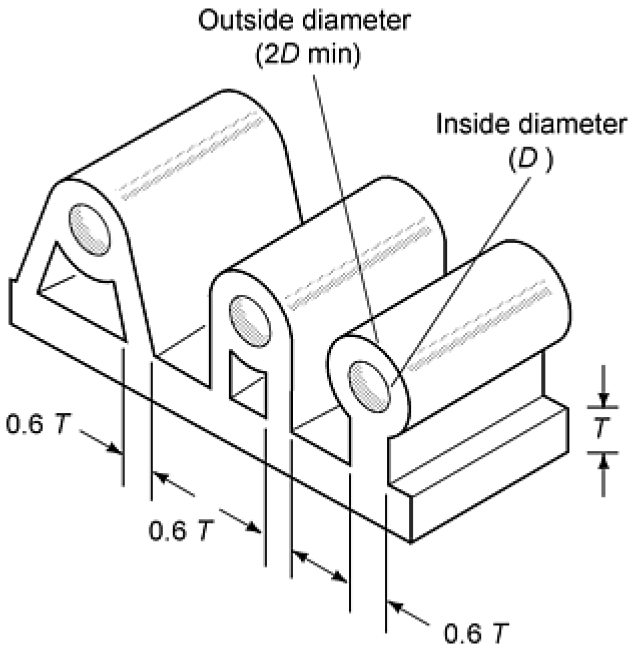

Fig. 9 Boss configurations for injection-molded plastic parts

Extrusion

The extrusion of plastic material is, surprisingly, the process that utilizes the most plastic material, even more than injection molding. One reason for this great material consumption is that extrusion is one of the few continuous plastics processes. Other plastics processes are batch processes, relying upon repetition. Extrusion of plastic material is continuous, and the plastic product is cut and formed in a secondary process. Another reason is that extrusion is used to compound and produce the plastic pellets used in most other thermoplastic processing operations. For example, most plastic pellets used in the injection molding process are produced in an extruder at the plant of the material manufacturer.

The extruded product is designed as a two-dimensional cross-section shape, which is extruded in the third dimension. The third dimension is usually controlled by a cut-off operation. As an example, polyvinyl chloride (PVC) pipe is designed as two simple concentric circles. A die is fabricated, and the plastic melt is extruded through the die on a continuous basis (Fig. 10a). The length of the pipe is defined and created by cutting the continuous extrudate to the desired length.

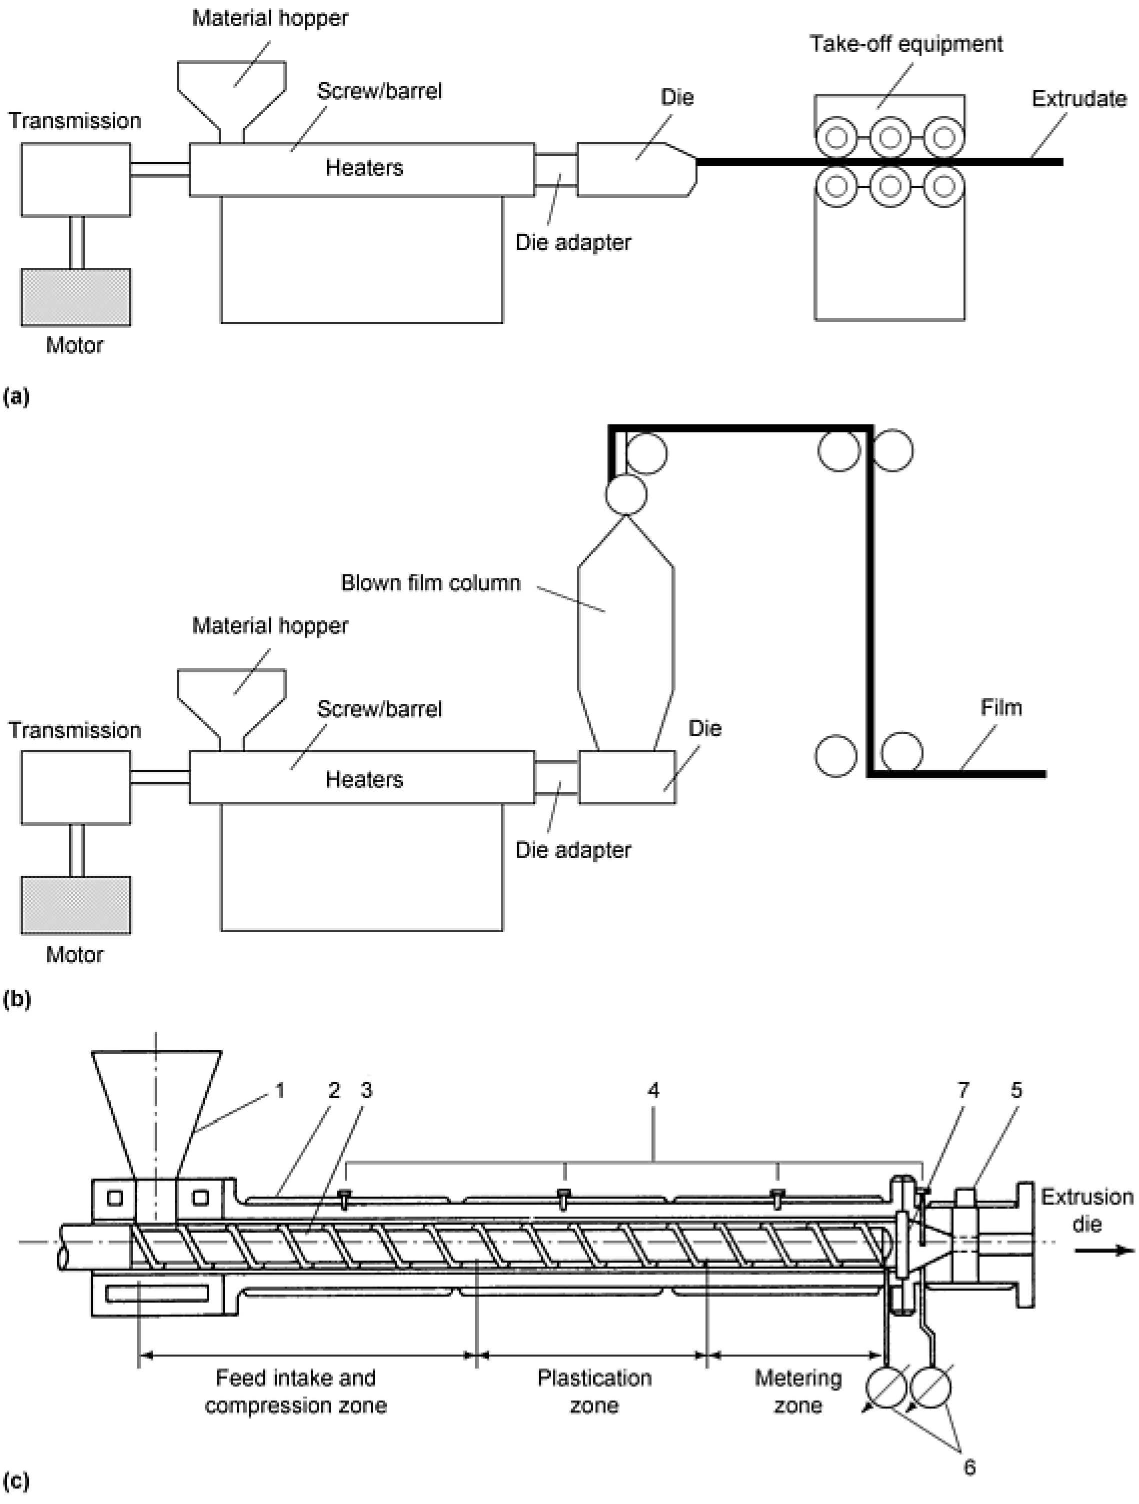

Fig. 10 Extrusion processes. (a) Profile/sheet extrusion. (b) Blown film extrusion. (c) Construction arrangement of the plastication barrel of an extruder. 1, feed hopper; 2, barrel heating; 3, screw; 4, thermocouples; 5, back pressure regulating valve; 6, pressure-measuring instruments; 7, breaker plate and screen pack

Types of extruded parts can be categorized as follows:

- *Sheet* is a flat extruded profile greater than 0.0004 mm (0.010 in.) thick.
- *Film* is a flat extruded profile less than 0.0004 mm (0.010 in.) thick. Blown film (Fig. 10b) is a volume product used for trash bags, packaging, and wrappings. Cast film is a high-volume, high-tolerance product used for carrier material in the printing and audio/video recording industry.

- *Profile* is a shaped extruded profile.
- *Fiber* is a cylindrical or tubular profile less than 0.0004 mm (0.010 in.) thick.

Details and design considerations for extruded parts include die swell and orientation.

Die swell (Fig. 11) is the phenomenon where an extrudate swells to a size greater than the die from which it came. As the plastic exits the die, it tends to swell. This is associated with the reduction in pressure as well as the nature of the polymer itself. Die swell has to be considered by the product designer as well as the die designer in order to produce extrusions that meet the customer requirements.

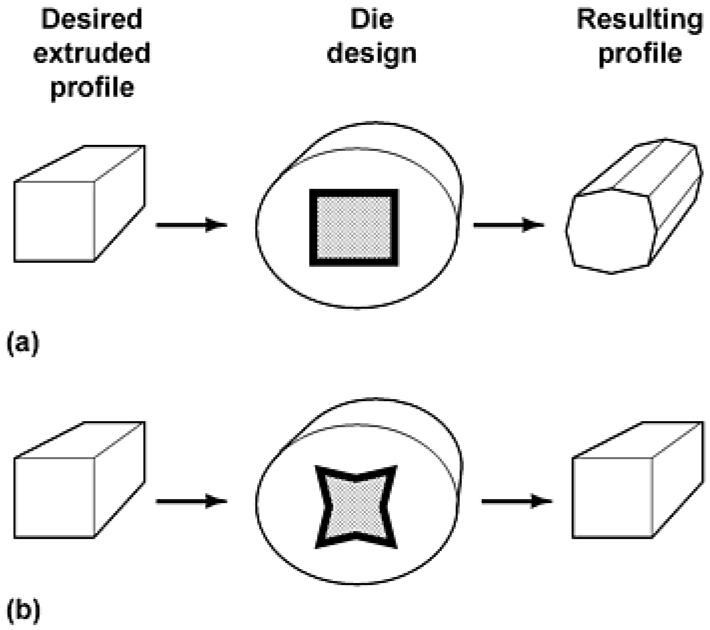

Fig. 11 Die swell in extrusion. (a) Incorrect die design for intended profile. (b) Correct die design

Orientation is the phenomenon where the polymer molecules are aligned as a result of the high degree of laminar flow as well as the pulling of the extrusion take-off apparatus. Orientation is often desirable, if controlled, because it can improve the properties of the extruded product. Biaxial orientation is orientation in two directions and improves strength in film materials.

Orientation also allows an extruded product to shrink when exposed to heat. Shrink-wrap materials for packaging and dunnage have become very important products that incorporate this phenomenon of shrinking due to controlled orientation and heating.

Thermoforming

Thermoforming, also referred to as vacuum forming, forms plastic sheet into shapes. The plastic sheet is placed into a clamp frame to hold it securely on all edges. The sheet material is placed into the clamp frame manually, robotically for high-volume processing, or continuously if the sheet material is produced by an in-line extruder. Thermal energy, usually in the form of convection and radiant heat from electrical heating elements, is applied for a sufficient amount of time to soften (not melt) the plastic sheet. Once the sheet is sufficiently softened, a mold is brought in contact with the sheet, and a vacuum is applied that draws the softened sheet onto the mold. After the sheet cools, it will retain the shape of the mold when the mold is removed. The thermoforming process sequence is shown in Fig. 12.

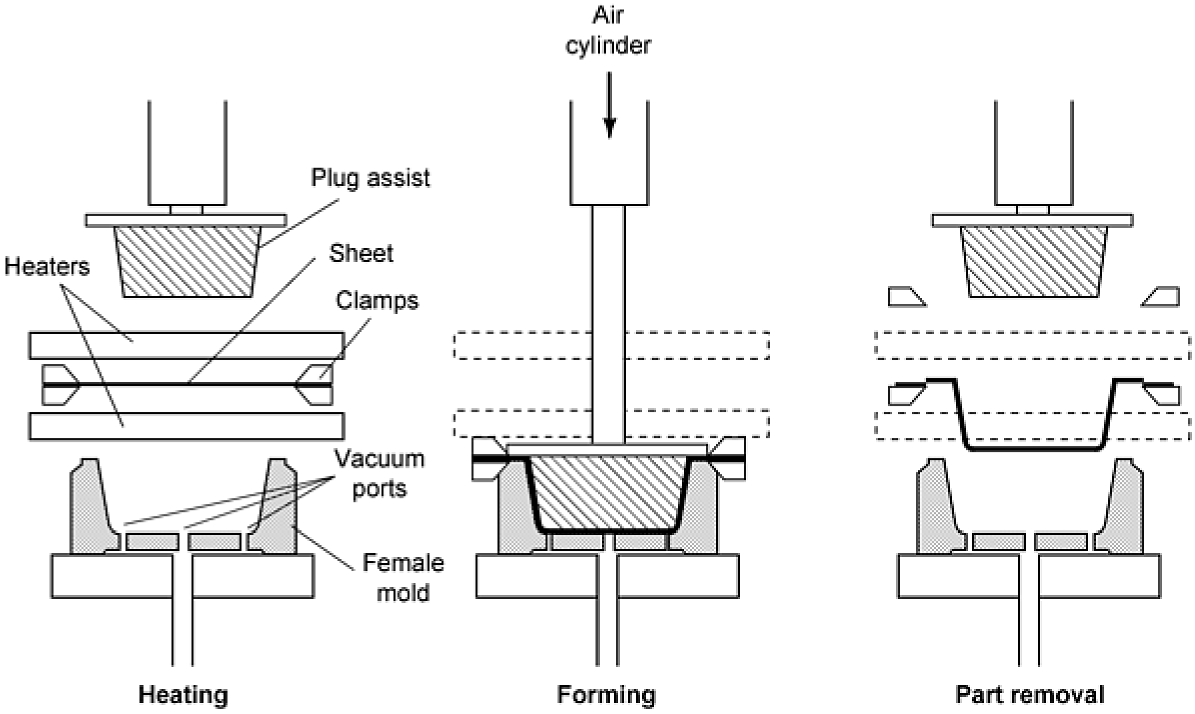

Fig. 12 Thermoforming (vacuum forming)

Historically, thermoforming has been considered a one-sided process, that is, the softened sheet will either conform to a male mold with the inside becoming the critical surface and the outside the noncritical surface, or conform to a female mold with the outside becoming the critical surface and the inside the noncritical surface. This one-sided approach to thermoforming was satisfactory for decades when the process was used primarily for simple packaging parts. Today, process advancements have enabled the production of thermoformed parts that have two critical sides and sufficient dimensional accuracy to allow them to be used in key automotive, building, and construction applications. This dimensional control is accomplished by having two dies or molds, one forming either side of the sheet.

Typical Thermoformed Parts. The majority of thermoformed products are produced for the packaging market; however, broader applications include:

- Blister packages
- Foam food containers
- Refrigerator and dishwasher door liners
- Auto interior panels
- Tub/shower shells, which are later fiber reinforced
- Pickup truck bed liners
- Internally lighted acrylic and cellulose acetate butyrate (CAB) signs

The thermoforming process offers some unique tooling advantages over other conventional plastic processes, primarily because the thermoform molds are relatively simple in design and construction as well as lower in cost.

Prototypes produced using the thermoforming process can be made quickly by using simple molds made from inexpensive materials, such as wood, plaster, and epoxy. Many designers will insist upon a product design review that includes the development of one or more thermoformed prototype parts.

Blow Molding

Blow molding has historically been associated with simple geometries such as bottles and containers. However, there have been significant developments in the blow molding process and its variants in the past two decades. These developments allow the blow molding of more complex shapes such as air ducts and automobile fuel tanks.

Basic blow molding equipment (Fig. 13a) is essentially a profile extruder attached to a blowing station. The extruder produces a tube referred to as a parison. The parison can be controlled in both its size and shape. At the blowing station (Fig. 13b), the mold captures the parison and seals it by pinching either end. A blow pin is then inserted into the parison, and air is introduced at about 700 kPa (100 psi). The air causes the pinched parison to expand and take the shape of the mold.

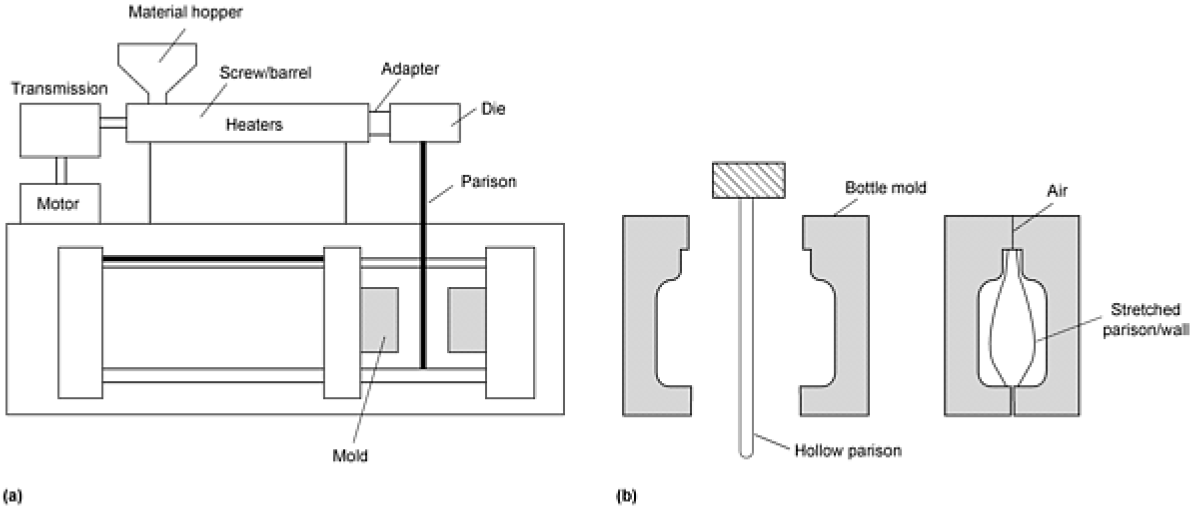

Fig. 13 Blow molding. (a) Equipment configuration. (b) Sequence at blowing station for a bottle mold

This basic process results in a product that is dimensionally defined on the exterior surfaces. The interior surfaces are not controlled as they do not contact a mold surface. As a result, the wall thickness of a conventionally blow molded part may vary. The nature of the conventional blow molding process also does not lend itself to incorporating design features such as holes, sharp corners, and narrow ribs.

Rotational Molding

Like blow molding, rotational molding produces a hollow product. Unlike blow molding, however, rotational molding is a relatively slow process that begins with plastic in the form of a powder, not a parison. The advantage of rotational molding is that it can produce large objects, with capacities from 1 to more than 500 gal. Additionally, the wall thickness is a function of how much plastic powder is placed into the mold, and thick (2.5 to 12 mm, or 0.10 to 0.4 in.) wall sections can be formed.

The rotational molding process uses a mold made of sheet metal or cast aluminum. Because rotational molding is a low-pressure process, tooling can be lower in strength than that used for the other molding processes.

Another advantage of rotational molding over other plastic processes is that it results in a very low stressed product. Since the rotational process is low in pressure, and the plastic is not forced through narrow channels, it does not induce a significant amount of internal stress. The result is a high degree of dimensional stability in the final product.

Processing Sequence. The plastic powder is placed directly into the mold by the operator. The mold is attached to the rotational process equipment where it passes through three distinct process stages: loading, heating, and cooling.

Loading is the stage of the process where the plastic powder is loaded into the mold and the mold is attached to the process equipment. After loading is completed, the mold begins to rotate along three axes. Although the rotation speed is relatively slow (<20 rpm), it is sufficient to force the plastic powder to the mold walls.

Heating is the stage of the process where heat, usually generated by a natural gas fired heater, brings the rotating mold to a temperature high enough to fuse the plastic powder.

Cooling is the stage of the process where the mold, which is still rotating, is allowed to cool, and the fused plastic in the mold solidifies. Once the contents of the mold are sufficiently cooled, the mold is separated and the product removed.

Processing Systems. Advances in the rotational molding equipment have resulted in two distinct styles of processing systems:

- *A conventional rotational system* has the mold located on the end of one of several arms. Several molds are at various stages of the process simultaneously.
- *A clam shell system* (Fig. 14) has the mold located on a rotating apparatus that is housed within a chestlike chamber. The clam shell system has a fixed and compact footprint. The chamber environment changes to heat as well as cool the mold. Especially good for small rotational molded parts, the clam shell system provides superior control and safety.

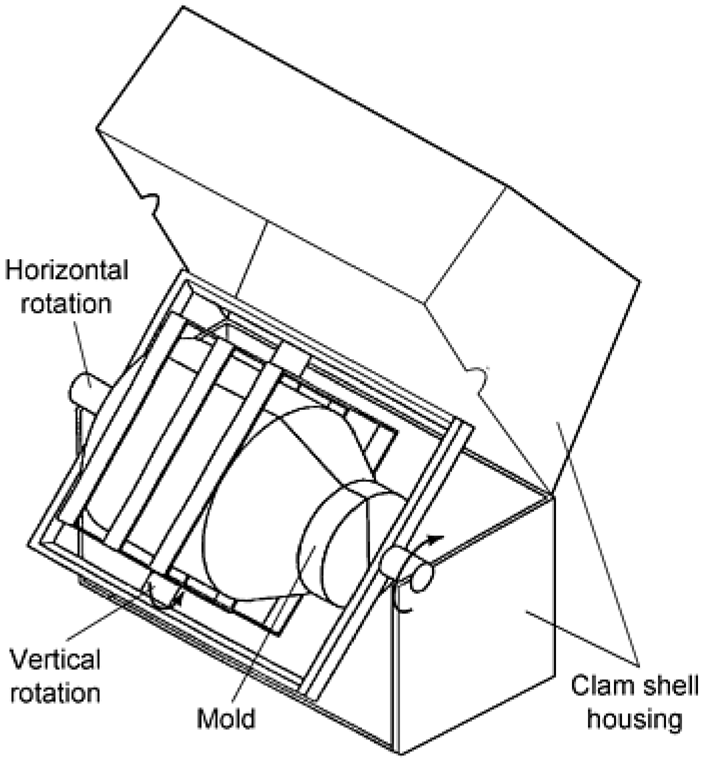

Fig. 14 Rotational molding equipment (clam shell type)

Compression Molding and Transfer Molding

Compression molding and transfer molding (a variant of compression molding) are two of the oldest plastic processing methods.

Compression molding is a simple process that offers the manufacturer an excellent method for producing low stress plastic parts. As shown in Fig. 15, the plastic material, usually in the form of a powder or preformed pill, is placed in the cavity or female section of the mold. Since most compression molding is associated with thermosetting plastics, the mold temperature will be relatively high (149 to 177 °C, or 300 to 350 °F). The male or core portion of the mold is located on the upper portion of the mold. After the plastic material is loaded, the male portion of the mold is lowered and compresses the heated plastic in the cavity. The heat and pressure cause the material to flow and fill the cavity details. In many compression molding processes, excess plastic forms a flash that will be removed in a secondary operation. The plastic material will then be allowed to cure or set, and the plastic part will be ejected from the mold.

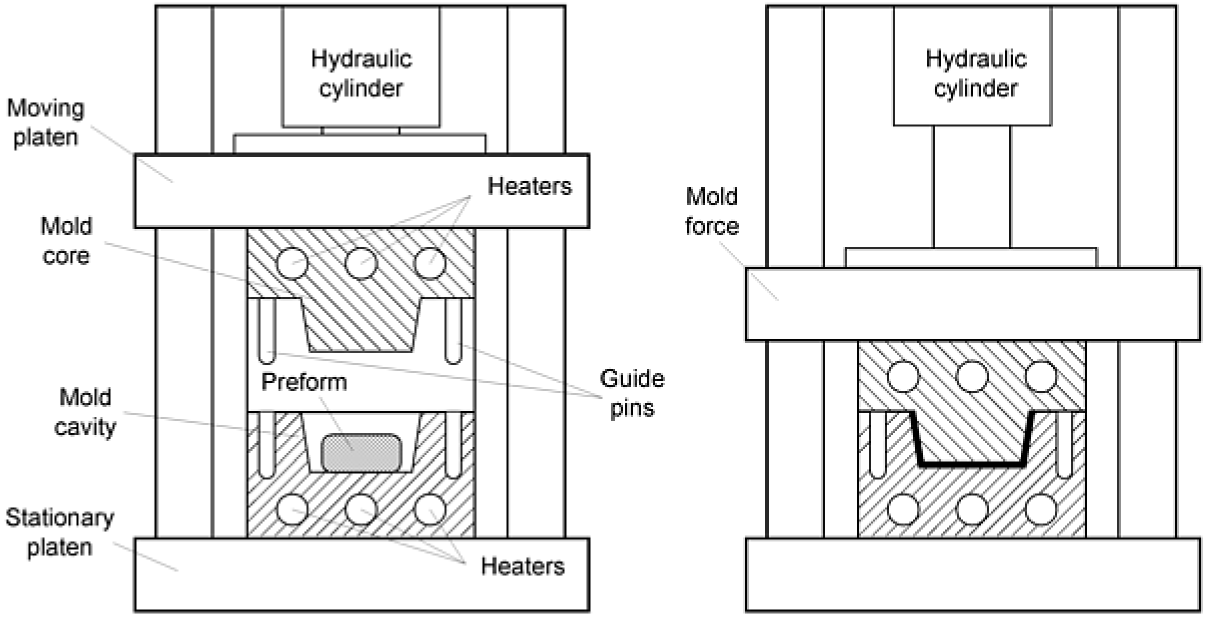

Fig. 15 Compression molding

Because the thermosetting plastic flows only a short distance and the flow rate is relatively slow, little shear stress is developed in the process. This low stress level will result in low internal or molded-in stress in the part, which thus will have a high degree of dimensional stability.

Transfer molding is a variant of the compression molding process and is a precursor to the modern injection molding process. The main difference between compression and transfer molding is in the method by which the plastic material enters the mold. As stated above, compression molding requires the material to be preloaded into the mold in the form of either a powder or a preform. Transfer molding utilizes a transfer ram or plunger where powder or preform is loaded into a chamber above the mold. The material in this chamber is forced through a sprue and runner/gate system to fill the mold. The transfer process allows the plastic to enter the mold in a molten or fluid state; thus, the process is adaptable to insert or overmolding. The downside of the transfer process is that there is often a need for secondary operations to separate the product from the gates/runners. There is also a certain amount of waste with the sprue and runners.

The ability to overmold or insert mold product allows many unique products to be transfer molded. These include electrical outlets, semiconductors such as integrated circuits, plastic handles for products such as knives, and plastic exteriors for metal parts.

Composites Processing

The term *composite* applies to plastic materials that are reinforced with glass, mica, metal, carbon fibers, or other materials. Composite materials provide the plastics part designer and plastics processor with the opportunity to customize a plastic compound by adjusting the type and volume of reinforcements added to a specific plastic matrix. Such composites usually exhibit synergistic behavior. Synergism, in the context of plastic materials, is when the strength of the composite is greater than the sum of the strength of the individual matrix and reinforcements. Additionally, composite plastics also distribute loads better than conventional plastics and result in superior strength-to-weight ratios. Other advantages of composite plastics are that they can be used to fabricate large parts and they offer excellent product durability and superior chemical resistance.

Although the development of composite materials and fabrication methods have made great strides over the past 20 years, there are very few high-volume processes available to manufacturers. Additionally, there are few design rules available to composite product designers. Products designed for conventional processes, such as injection molding, blow molding, extrusion, and thermoforming, can utilize a series of design guidelines based on an understanding of the materials and processes involved. Since composite product fabrication was limited, these design guidelines are still being developed.

Some other disadvantages of composite processing include high product cost, high equipment cost (and limited availability), and low production rates.

Composite production processes include casting, reaction injection molding (RIM), structural reaction injection molding (SRIM), resin transfer molding (RTM), matched metal molding, filament winding, and pultrusion. Some of these processes are also used for noncomposite materials; casting is described separately below in the section "Casting" in this article.

Reaction injection molding is a variant of injection molding (described previously in the section "Injection Molding" in this article). It is used for molding polyurethane, epoxy, and other liquid chemical systems. Mixing two to four components in the proper ratio is accomplished by a high-pressure impingement-type mixing head, from which the mixed material is delivered into the mold at low pressure, where it reacts (cures).

Structural reaction injection molding is in its technological infancy. As a consequence, the process is undergoing dramatic material and process improvements and rapid industrial growth. In many ways, SRIM is the natural evolution of two more established molding processes: RIM (described above) and RTM (described below). Like RIM, SRIM uses the fast polymerization reactions of RIM-type polymers, its intensive resin mixing procedures, and its rapid resin reaction rates. Like RTM, SRIM also employs preforms preplaced in the cavity of a compression mold to obtain optimum composite mechanical properties. A schematic of the SRIM process is shown in Fig. 16.

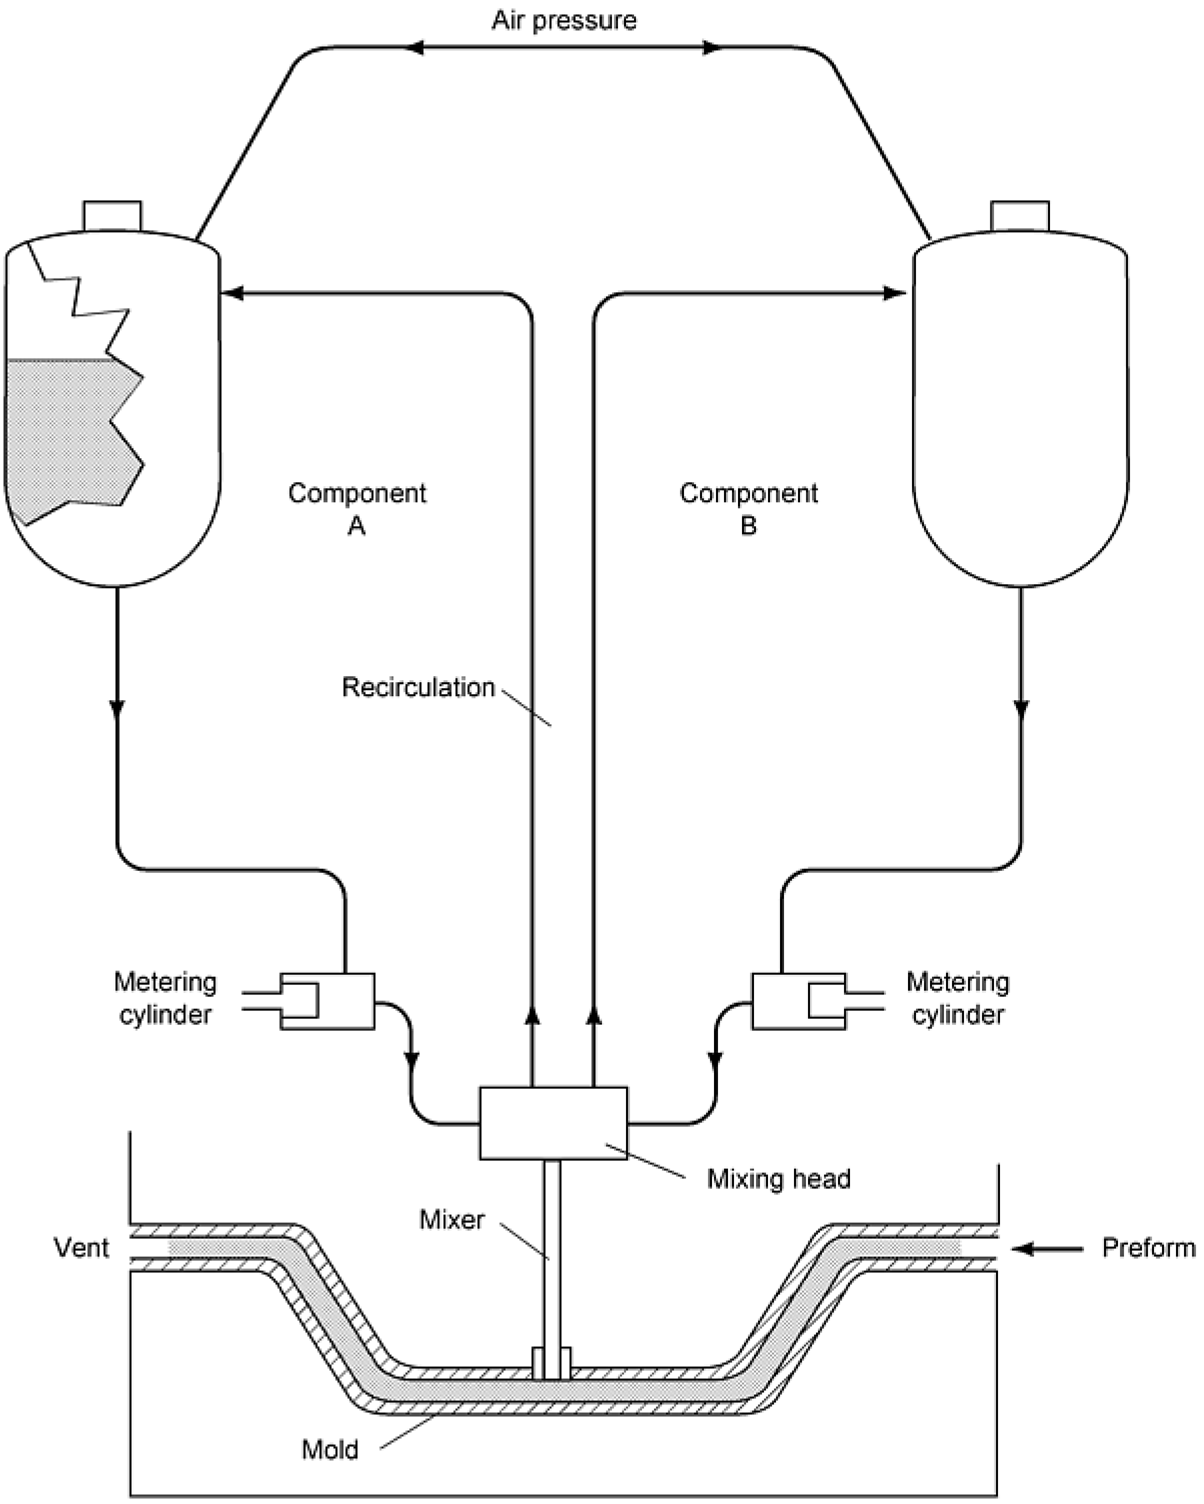

Fig. 16 Schematic of the structural reaction injection molding process

The ability of SRIM to fabricate large, lightweight composite parts consisting of all types of precisely located inserts and selected reinforcements is an advantage that other competitive manufacturing processes find difficult to match. In addition, large SRIM parts can often be molded in 2 to 3 min with clamping pressures as low as 700 kPa (100 psi). Thus the capital requirements of SRIM are relatively low, allowing the economical manufacture of parts with annual production volumes below 10,000 units. These advantages, when coupled with the concurrent development of a large family of commercially available SRIM resins, have led to predictions of a high SRIM annual growth rate.

Applications of SRIM. The first SRIM part commercially produced was the cover of the spare tire well in several automobiles produced by General Motors. Other SRIM automotive structural parts include foam door panels, sunshades, instrument panel inserts, and rear window decks. Nonautomotive SRIM applications include seat shells for the furniture market and satellite dishes for home entertainment centers.

Structural reaction injection molding is an attractive process for the economical production of large, complex structural parts. The main drawback of this process is that it is relatively new so that some aspects of this technology are poorly understood and some crucial equipment remains to be fully developed.

Resin transfer molding is a process by which catalyzed resin is transferred or injected into an enclosed mold in which reinforcement has been placed (Fig. 17). The fiberglass reinforcement is usually woven, nonwoven, or knitted fabric. Resin transfer molding is primarily used for prototyping; low-volume production of large, relatively complex parts; or low-to-medium-volume production of small, simple parts.

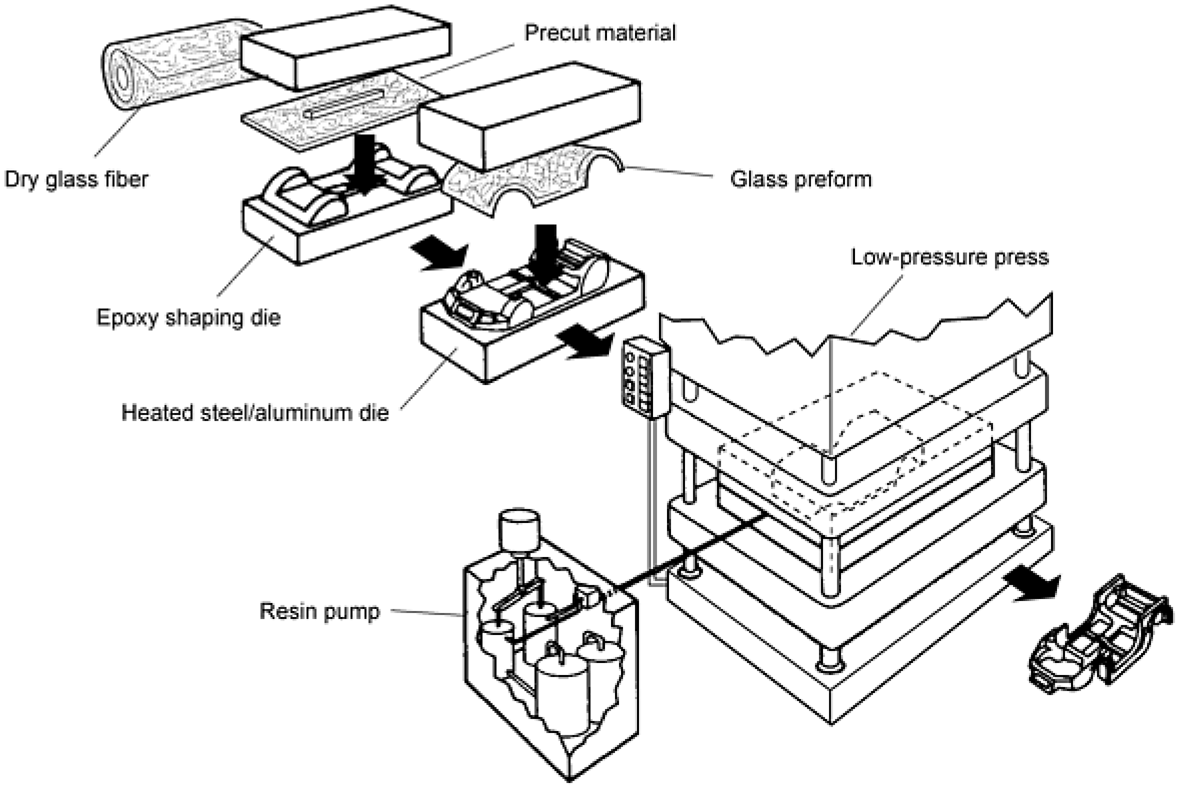

Fig. 17 Schematic of the high-speed resin transfer molding process

Prototyping. Resin transfer molding is an excellent process choice for making prototype components. Unlike processes such as compression molding and injection molding, which require tools and equipment approaching production level to accurately simulate the physical properties achievable in the production level component, RTM allows representative prototypes to be molded at low cost. It should be noted that in some cases, RTM can be used to prototype components designed for other processes; the RTM component will typically have properties that exceed those of the production-level product.

When prototyping with RTM, less reactive resins are generally used allowing long fill times and easier control of the vents. Tooling is usually low-cost epoxy, but could be made with an impervious material that would contain the resin. Prototype preforms are made by cut-and-sew methods, and any foam cores used are machined to shape. Sizes can range from small components to very large, complex three-dimensional structures. RTM provides two finished surfaces and controlled thickness, and it requires no auxiliary vacuum or autoclave equipment. Other processes used for prototyping such as hand layup and wet molding give only a single finished surface, and dimensions in the thickness direction are controlled.

Matched metal molding, also known as matched-die press forming, is the most common and probably the most widely used composites forming system. This is because forming presses are readily available from very simple, hand-operated small presses to fairly sophisticated, computer-controlled hydraulic systems. For simple forming operations, standard heated platen presses that have generally been used for flat panel molding have proven to be adequate. However, in operations where the control of deformation rate and pressure history are important, high quality stamping presses are used.

The dies used in this forming method are generally made of metal, which can be internally heated and/or cooled. When metals are used, the dies are generally designed to fixed gap (thickness) of close tolerance. High pressures can easily be applied to the workpiece. A disadvantage of this forming method is that when there is a thickness mismatch between the formed piece and the premachined cavity, nonuniform pressure is produced on the part resulting in nonuniform consolidation.

When heating or cooling is desired, the dies usually have such a high heat content that heat transfer times are long. Finally, matched-die fabrication costs are high because of the requirement that the two close-tolerance die halves have to match. Substituting an elastomeric material for one of the die halves will usually reduce the tooling cost and enable the application of a more uniform consolidation pressure than in an all-metal die set.

Pultrusion (Fig. 18) is a composite process that has many similarities to extrusion. Pultrusion begins with strands of reinforcement, usually glass or carbon fibers, that have been wetted in a resin tank. The resin used is most often an epoxy or polyester. The next step in the process is to pull the resin-soaked strands through a heated shaping die. The die may be in the shape of a rod, tube, I-beam, or other geometric shapes. After the resin is cured and pulled through the die, the resulting profile has a high strength-to-weight ratio and is very durable, especially in a chemical environment.

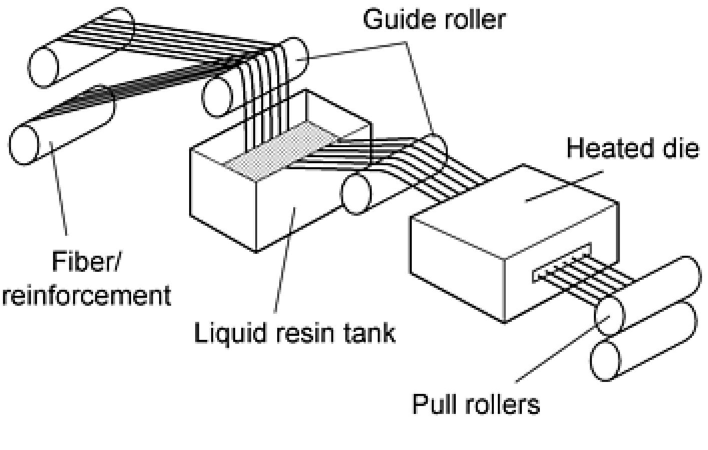

Fig. 18 Pultrusion

Applications for pultruded products include structural beams for electrical and chemical environments (for example, ladders for use near electrical wires), poles, and shafts. The future of the pultrusion process may be in space applications where long structural components for space stations could be manufactured in space, as required, eliminating the need to transport long beams from earth.

Filament winding is primarily used to manufacture large structural containers or tanks. The process involves several spools of reinforcing materials such as glass or carbon strands. The strands are directed into a resin bath of either polyester or epoxy. The wetted strands are wound over a turning mandrel (Fig. 19) in different patterns to provide

different strengths. After the resin has cured, the filament wound part is removed from the mandrel and machined or assembled as required.

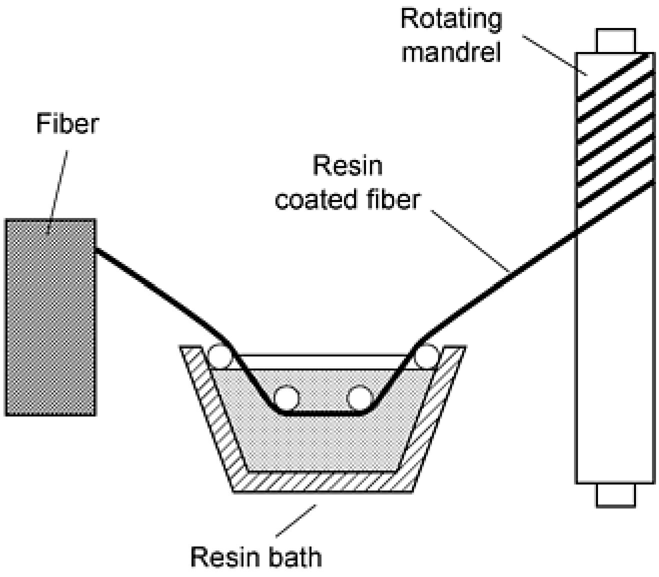

Fig. 19 Filament winding

Applications for filament wound composites include gasoline storage tanks, septic tanks, large-diameter drainage pipes, chemical storage systems, and sporting equipment such as golf club shafts and bike frames.

Additional information about composites processing is provided in the article "Design for Composite Manufacture" in this Volume.

Casting

Casting is the process of pouring liquid plastic into a mold. The recent development of a wide variety of casting resins and rapid tooling fabrication has allowed the casting process to be considered as a viable process for both prototyping and low-volume production. Typical casting resins include casting acrylic, casting polycarbonate, epoxy, polyurethane, and polyester. The casting process produces plastic parts with the lowest level of internal stress and a high degree of dimensional stability.

Design Features and Process Considerations

A design feature is an aspect of the shape of a product. Principal features incorporated into the design of a plastic part are:

- *Walls* are the predominant features of the shape of a product. The nominal wall for a plastic part is the platform on which all other design features reside. Most other design features are configured and sized as a function of the size of the nominal wall (Fig. 20).
- *Projections* are design features that rise from the nominal wall. They include ribs, gussets, threads, snap-fits, and bosses (Fig. 21).
- *Depressions* are design features that enter into or reside within the nominal wall. They include through

holes, blind holes, and slots (Fig. 22).

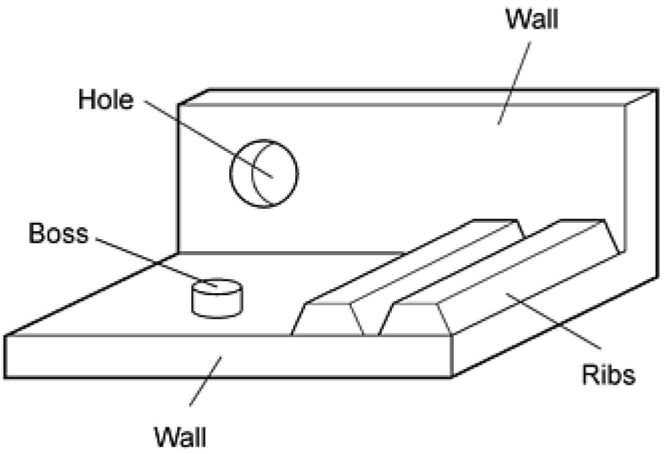

Fig. 20 Plastic part wall components

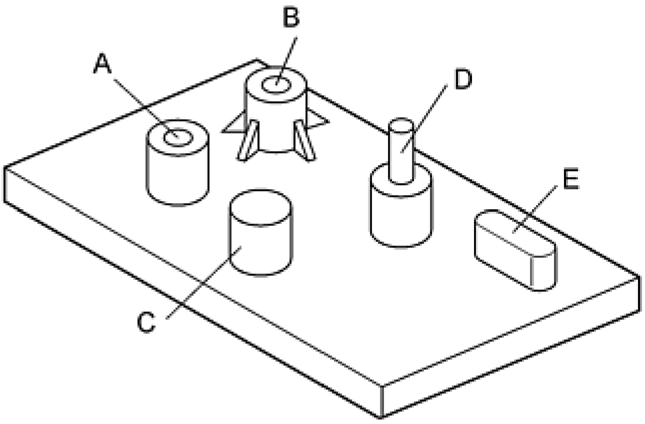

Fig. 21 Boss designs for plastic parts. A, hollow boss; B, gussetted boss; C, solid boss; D, stepped boss; E, elongated boss

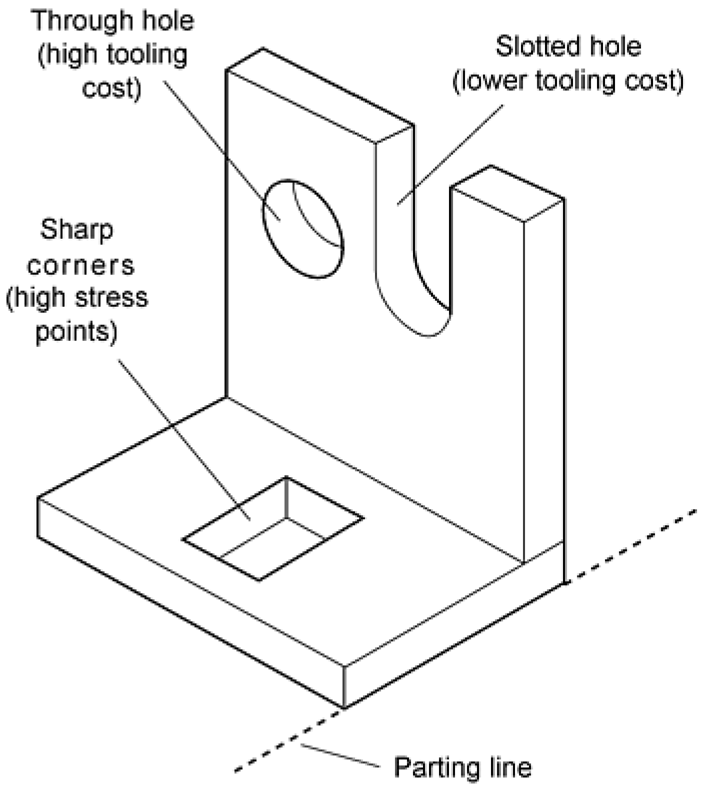

Fig. 22 Depression designs for plastic parts

Design for assembly (DFA), or design for manufacturing and assembly (DFMA), is a design methodology that embraces the concept that well-engineered assemblies will take advantage of the high functionality of materials, such as plastics, and integrate several design features, such as snaps, alignment features, and locks, to facilitate assembly. These integral features help to eliminate conventional assembly components such as screws, washers, and nuts. Additionally, the product designers that utilize DFA techniques go beyond the design of the individual part to consider the optimization of the design of several parts in an assembly (Fig. 23). General DFA concepts are described in the articles "Introduction to Manufacturing and Design" and "Design for Manufacture and Assembly" in this Volume.

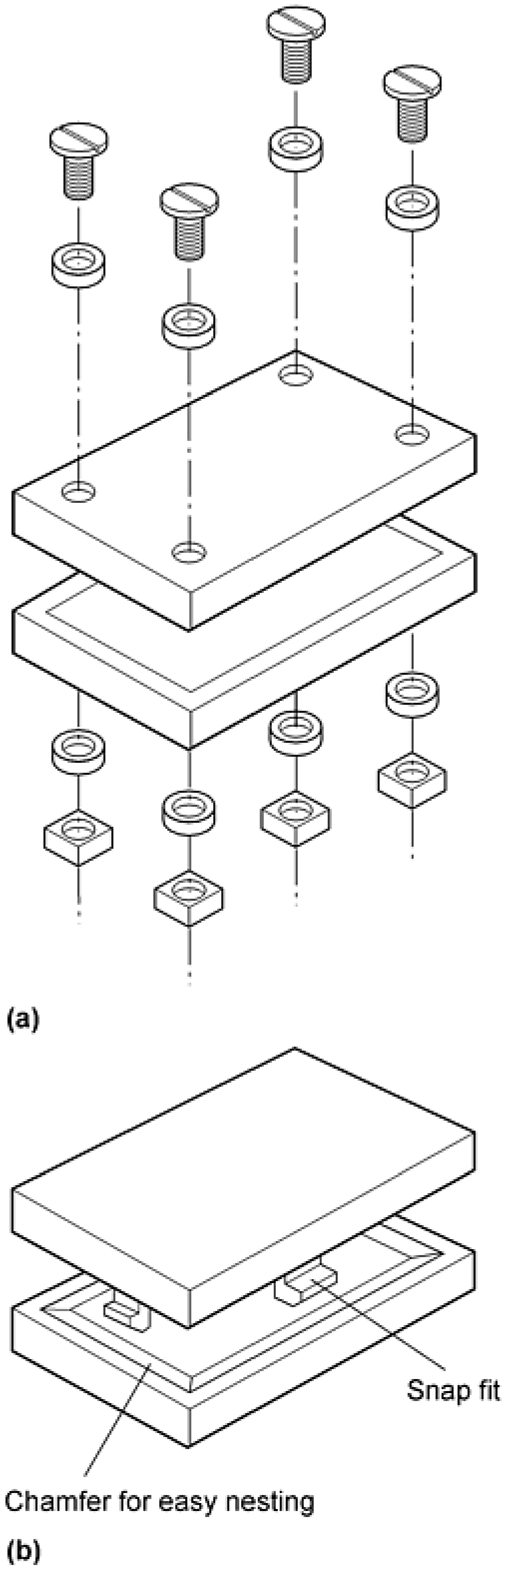

Fig. 23 Designing for product assembly. (a) Original design. (b) Improved design for ease of assembly

Design for Optimum Properties and Performance. While many product designers understand that it is possible to degrade or lower material properties through processing operations, opportunities to optimize properties of the plastic and the plastic product are often overlooked. The most important step in the optimizing process is to understand how the properties of a plastic will vary when processed and to alter the product design to avoid or manage this variation.

The best resource for determining these variations is direct experience. Certainly, material suppliers can provide generalizations as to the effects of processing; however, there are simply too many variables (design, process equipment, additives, etc.) for detailed and reliable property variations to be published.

An example of such a property variation is a polycarbonate part designed for high-impact strength that has a wall section that is too thick. The polycarbonate shows impact degradation at a critical thickness value; thus the impact properties of the resulting plastic product may be much lower than those published by the material manufacturer.

A second example is a polyacetal part molded with a low mold temperature, to improve the cycle time, resulting in an induced stress level and postmold shrinkage. The product may be dimensionally correct when measured directly after molding but too small when inspected 1 week later after delivery to the customer.

A third example is a polyphenylene sulfide part processed with a mold temperature of 93 °C (200 °F), the highest temperature the molder's water controller can safely attain. As a result, the polymer does not achieve optimum crystallinity, and the part performance suffers in its end-use application. While water-heated molds may be acceptable for many plastics, the molder did not recognize that an electric or oil-heated mold would have allowed a more appropriate mold temperature of 121 °C (250 °F) to maximize the crystallinity of the polymer.

Design for Plastics Processing

Edward A. Muccio, Ferris State University

Other Plastics Design and Processing Considerations

Stress in plastic parts is most often related to shear stress, especially for molded or extruded parts. During molding, a plastic part is subjected to a rigorous process environment. When melted plastic is forced into a closed mold, three major stress contributors are present: high pressure, high speed, and constricted flow areas.

The stress level in a part depends on the processing method used. The three major stress-producing components are present in injection molding; thus injection-molded parts usually have a high degree of molded-in stress. Compression molding usually has only the high-pressure component and thus produces parts with much lower molded-in stress.

Casting involves none of the major stress-contributing factors and, therefore, results in parts with the lowest levels of molded-in stress.

Stress levels, in a plastic part, affect the properties and performance of the product. In general, as the molded-in stress level increases, dimensional stability decreases, chemical properties lower, mechanical properties decrease, and optical properties diminish. A good example of this relationship is the compact disc (CD). A CD needs to be optically pure and mechanically strong. For efficient production, the best processing method for CDs is high-volume injection molding. However, by its nature, the injection molding process will lower the required properties, especially because the discs are extremely thin and will promote high shear stress. This problem was solved, in large part, by the development of a low-viscosity plastic (polycarbonate) that required lower molding pressures to fill the mold and thus lowered the resulting molded-in stress in the CDs.

Published versus Actual Product Properties. It is technically naive to believe that the material manufacturer's published properties will be duplicated in the final product. Published properties are derived from parts that are molded and tested under highly controlled conditions. The environment is controlled to either "dry as molded" or 50% relative humidity conditions. The samples tested are usually ASTM/ISO test specimens that do not have the design features that often can serve to lower properties in molded products.

The property effects of additives such as colorants and regrind are often not published simply because there are too many variables involved. Also, time-related properties such as weatherability and creep often are interpretive, and published data should serve only as guidelines for the designer.

It is important that the product design team along with the manufacturing team develop and test the plastic products prior to production. Using the manufacturer's published data as a reference, the product tests should always emulate the end-use application environment as closely as is practical.

End-Use Concerns. Even well-designed and manufactured plastic products can fail because one or more aspects of the end-use application was not considered. The longer the list of end-use environmental conditions that are assessed and respected, the more successful the plastic product will be.

Many new plastic product designers tend to focus on details, but overlook some obvious end-use considerations. Examples include:

- Effects of household chemicals (for example, milk, water, cleaners, makeup, and makeup removers) on plastics used for consumer applications
- Shipping and handling factors (for example, high compartment temperatures and damage from dropped boxes)
- Time-related issues such as creep, stress relaxation, and ultraviolet weatherability

Design for Plastics Processing

Edward A. Muccio, Ferris State University

Materials Selection Methodology

Selecting a plastic material for a specific end-use application is a challenge. It requires a thorough understanding of the end-use application, a knowledge of available plastic materials and their properties, and a methodology to sort and select all the data to make a prudent decision.

Understanding the End-Use Application. As noted above in the section "Other Plastics Design and Processing Considerations," it is important for the designer to understand the intended application of a part including physical loads that will be applied, chemical resistance and exposure factors, and temperature. However, a designer must investigate the end-use environment even further if a good material selection is to be made.

For example, a design specification from a furniture maker noted that their products typically experience temperatures between 16 and 27 °C (60 and 80 °F). This is a narrow range, but the furniture maker understood that their customer base would always properly control the environment of the office where the furniture was to be located. However, the shipping and storage of the furniture was overlooked. Temperatures in the back of a semitrailer truck or a warehouse can be significantly different from those in the ultimate end-use environment. Temperatures below freezing and over 43 °C (110 °F) are certainly possible. The plastic materials selected for this application must be able to withstand the shipping and storage as well as the end-use application.

In another example, a manufacturer carefully studied the end-use requirements for a new taillight lens and designed and processed the part to meet the requirements. The plastic lenses were molded in Texas and shipped (by truck) to the automaker in Detroit. The automaker was dismayed to discover upon delivery that more than 20% of the snap tabs used to hold the lens in its assembly were cracked or broken. The cause of the problem was the cyclical loading that occurred during shipping, which was different from any loading tested for the end-use application of the part.

A third and final example involves plastic material selection for a simple coat hook. The design engineer assessed the end-use application and determined that a 10 lb coat hanging for 8 to 10 h on the hook would be no problem. However, it was later discovered that the same 10 lb coat left on the hook for 30 days resulted in unacceptable deformation of the hook. The designer failed to consider the time-related phenomenon of creep.

Understanding the Properties of the Plastic Material. Thousands of plastic materials are available today, and the list is growing rapidly. It is challenging for designers to select the right plastic material, that is, one that meets all the property, processing, and cost requirements and goals. The material selection process is further complicated by the fact

that much of the information published about plastic materials focuses on their positive attributes. Very few plastics manufacturers overtly comment on the weaknesses or drawbacks of their materials.

Selecting a plastic material requires an understanding of the balance of properties; that is, how well a material meets the overall property requirements for a particular application and any effects that different properties may have on one another. For example, for a plastic material considered for a roof gutter system on a residential building, the properties that might be assessed include water resistance, impact resistance, temperature resistance (resistance to heat and cold), and weatherability (ability to withstand the rigors of outdoors).

Unfortunately, however, a simple list of attributes, although an excellent starting point, is not adequate to differentiate among the thousands of plastic materials available in order to make a proper selection. The selection process must have more depth. Consideration must go well beyond attributes and consider the specific variable or number value of each property. Once that is determined, there must be an assessment of interaction.

A more detailed property assessment might appear as follows:

Property	Requirement
Water resistance	Must not absorb >0.05% water when exposed to 100% humidity
Physical properties	Must be measured at 50% relative humidity
Impact resistance	Izod notched impact strength must be >133 J/m (>2.5 ft · lbf/in.) from -17 to 66 °C (-20 to 150 °F)
Temperature resistance	Temperature range is -40 to 71 °C (-40 to 160 °F)
Weatherability	<5% degradation in physical properties after 15 yr ultraviolet exposure (UVA and UVB)

It is clear that the process of identifying the end-use application requirements is more challenging than it may initially appear.

Other end-use properties that should not be overlooked include:

- Cost (material, labor, overhead, and yield)
- Processability (easy or difficult, inexpensive or costly)
- Maintenance (low or high, durability)
- Ease of assembly

While some of these attributes are a direct function of the product shape and design, the material selection aspect needs to be considered. As an example, when considering ease of assembly, it may be important to have a plastic material that can be bonded using solvents. This requirement would eliminate many plastics from the list that might otherwise have been candidates.

Material Selection Matrix. In order to simplify the material selection process, many product designers utilize a material selection matrix (Fig. 24). The matrix allows a direct comparison between the end-use properties desired and the actual properties available from the candidate materials. Additionally, the matrix helps prioritize and sort these properties to make the final selection.

Desired properties	Rating	PE	PP	PVC	ABS	PS	
Impact strength	9	3	4	5	2	1	Rank
		27	36	45	18	9	Rating × rank
Low cost	6	5	4	3	2	4	Rank
		30	24	18	12	24	Rating × rank
Flexural modulus	3	1	2	3	4	5	Rank
		3	6	9	12	15	Rating × rank
Low flammability	9	2	3	5	4	1	Rank
		18	27	45	36	9	Rating × rank
Tensile strength	6	2	3	4	5	1	Rank
		12	18	24	30	6	Rating × rank
Total (sum of products)		90	111	141	108	63	

Fig. 24 Example of a material selection matrix. PE, polyethylene; PP, polypropylene; PVC, polyvinyl chloride; ABS, acrylonitrile-butadiene-styrene; PS, polystyrene

Developing a material selection matrix involves a number of steps:

1. Identify as many material properties and attributes as possible that are required to meet the demands of the application.
2. Assign a rating to each property and attribute (where 9 is critical, 6 is desirable, and 3 is optional).
3. List the candidate materials.
4. Rank the materials, relative to one another, as to how well they meet each property/attribute requirement. (If there are four materials being compared, the material that best meets the property/attribute requirement receives a 4. The material the least meets the property/attribute requirement receives a 1.)
5. Multiply the property rating by the material ranking.
6. Add the products of Step 5.

The material with the highest sum is the top candidate. In Fig. 24, for example, PVC is the top candidate for the application represented by this matrix. This matrix analysis tool also can be readily adapted to compare processes as a means for optimizing process selection.

Design for Composite Manufacture

Anthony J. Vizzini, University of Maryland

Introduction

THE USE OF COMPOSITE MATERIALS provides the designer with great flexibility with which to meet part performance requirements. Even after a composite material has been selected, the design must still address the microstructure of the component. The type of reinforcement--continuous fiber, short fiber, whiskers, chopped roving, woven or braided fabrics, or preforms--and its orientation greatly affect the performance of the component. Indeed, the ability to tailor a component increases its range of functionality as well as the complexity of the design. For example, the skin of an aircraft wing near its root may involve a hundred plies. Although the plies may all be the same material in the same format, it is the collective orientations of the plies that yield the desired extensional, flexural, and torsional stiffnesses (Ref 1). The design at the microscale is more important than the simple orientation of the reinforcement. Failure mechanisms such as delamination, fiber microbuckling, fiber kinking, and transverse cracking all occur on the microscale and are sensitive to manufacturing variations (Ref 2).

Just as the design must address the microstructure, it must also address the macroscale. Composite materials can be formed into near-net shapes. Construction of components that often require many individual parts can be made in one step. Stiffeners can be staged, cocured, precured and integrated, or bonded. Sandwich construction with honeycomb or foam results in lightweight alternatives to stiffened panels. As the part count is reduced, the complexity of the components is increased. The structural design may be as extensive as the aft fuselage of the V-22 Osprey (built by Boeing Defense and Space Group, Helicopters Division) or as simple as composite dimensional lumber made from recycled plastics.

Designing composites for manufacturing is more extensive than being able to fabricate a part within specified dimensional tolerances. Indeed, the desired orientations of the reinforcement must be met with special attention paid to the presence and effects of anomalies or defects. Moreover, the prospect of large, integrated structures necessitates designing the manufacturing process concurrently with the component.

Design for Composite Manufacture

Anthony J. Vizzini, University of Maryland

Composites Manufacturing Processes

Often the design of a composite component is done in tandem with an equivalent metallic component to assess the cost/benefit of alternate materials. This could result in an unfair comparison as the designer employs such constraints as *black aluminum,* the use of quasi-isotropic layups to degenerate the behavior of an orthotropic material to that of an isotropic material. Or the designer develops the manufacturing process of the composite component concurrently with that for the metallic component. This design process does not take into account the tailorability of the composite material nor the potential advantages of the manufacturing process to increase performance, lower part count and weight, and decrease overall costs. The differences between composites and the materials they would potentially be replacing are significant enough to warrant independent development of the component and the manufacturing process.

Prior to the design of the composite component, many constraints may be imposed. Selection of the manufacturing process may be automatic based on available equipment and prior experience. The number of parts to be made is known, thus limiting the time to manufacture and the expected costs per part. Overall dimensions (such as those for a boat hull) or dimensional constraints are specified. Surface finish and dimensional stability may be specified. The operating environment and general loadings should be known. Thus, many selections are made prior to the actual design of the component. The material system is most likely chosen based on the operating temperature, desired mechanical properties, material availability, and cost considerations. The manufacturing process is selected based on surface finish, cycle time, and part cost.

The choice of material greatly influences the ability to design for manufacturing. The greatest latitude is afforded by polymeric resins. Structures that require ceramic, metallic, or carbon matrices involve forming processes that introduce matrix into the reinforcement. In metal-matrix composites, for example, reinforcements increase strength, decrease the coefficient of thermal expansion, and improve wear resistance at a cost of a reduction in ductility and in fracture toughness. Thus, the design of a component often begins with the manufacturing process itself and extends the available technology to incorporate the reinforcement. The goal is to improve the overall performance of the metal or ceramic matrix rather than to create a material with different response than the base matrix. Thus, this article concentrates on design for manufacturing of polymeric composites.

Thermoplastics that are reinforced with short-chopped, randomly oriented fibers are easily fabricated using conventional techniques. Injection molding and extrusion are widely employed. Composites based on thermosetting plastics are processed using specially developed methods, including:

- Contact molding, which employs single-surface molds, as in hand lay-up, spray-up, and filament winding
- Compression-type molding, as in sheet molding, bulk molding, preform molding, and cold molding
- Resin-injection molding, which is similar to the process used for nonreinforced materials and reinforced thermoplastics
- Pultrusion, which is a modification of the extrusion process

Each of these methods is briefly described below. More detailed information can be found in *Composites,* Volume 1 of the *Engineered Materials Handbook* published by ASM International.

Contact molding processes are used for liquid resin systems and various forms of fibrous reinforcement. As shown in Fig. 1, a mixture of the resin (liquid monomer and catalyst) is applied in liquid form to the mold. The reinforcing phase is usually placed in the mold in the form of a mat, a woven-roving cloth, or a preformed fibrous shape. The reinforcement is saturated with the liquid resin, which is then cured by heating. A male or female single-surface mold is used, thus providing only one smooth surface. The mold is first coated with a release film to prevent the finished part from sticking permanently. A thin (about 0.4 to 0.5 mm, or 0.015 to 0.020 in.) pigmented gel coat is then sprayed onto the mold surface to provide a smooth finish.

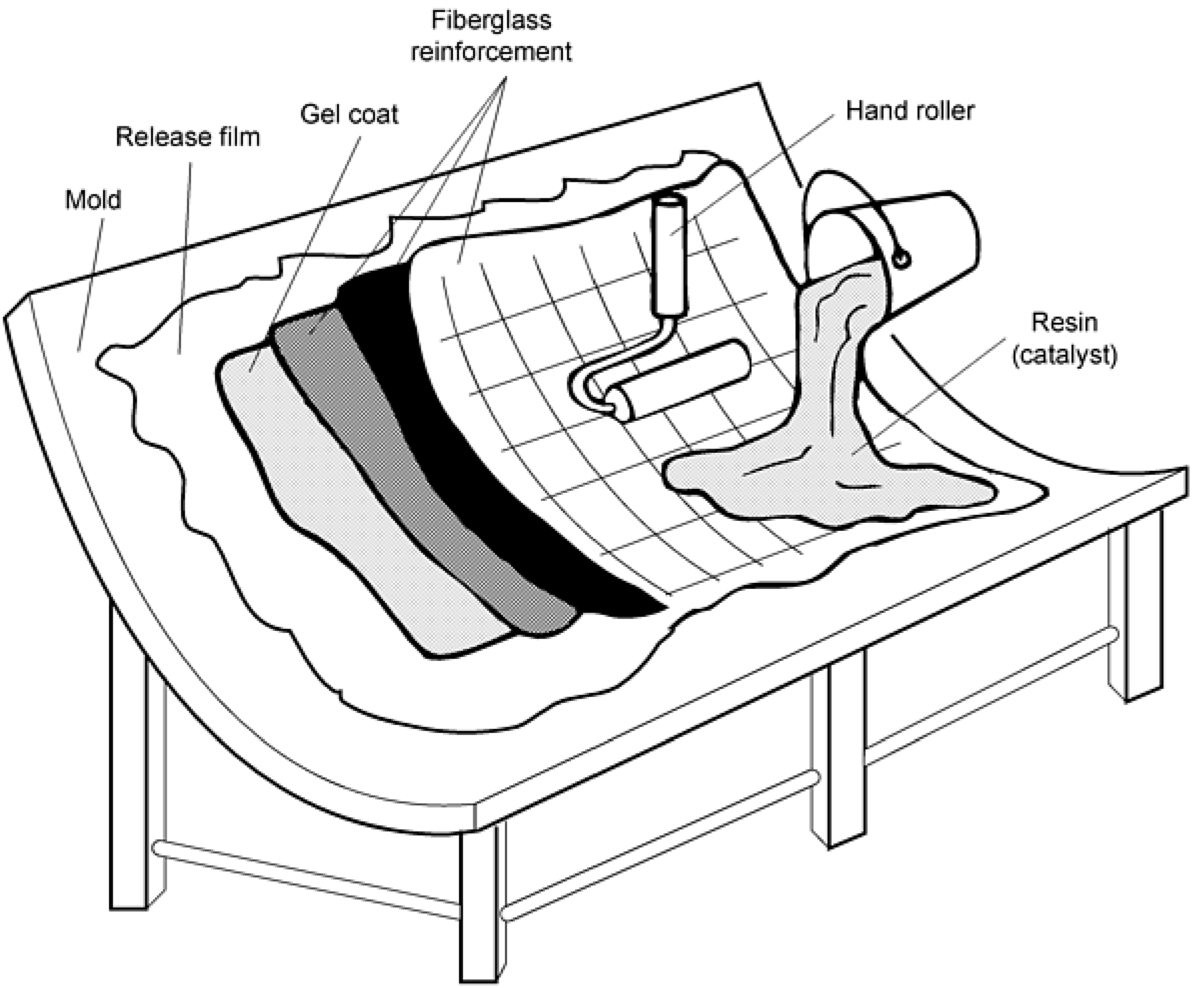

Fig. 1 Hand lay-up process for fabricating a boat hull

Hand lay-up is used for manufacturing low-to-medium production volumes of large, relatively thin-walled parts, such as boat hulls (Fig. 1). Spray-up uses a continuous-strand glass roving that is fed through a combination fiber chopper and spray gun. The chopped roving and liquid resin are sprayed on the mold surface to build up the required wall thickness. Curing under pressure can be achieved by placing pressure bags over the surface of the molding.

Filament winding is used for manufacturing highly reinforced (50 to 60% fiber volume fraction), high-strength parts, which are usually axisymmetric in shape. Continuous strands, roving, or woven tapes are drawn through a resin bath and wound onto a rotating mandrel (Fig. 2). The wound part is then cured by heating. Prepreg, in which the fibers have been coated with resin and stored at low temperature, can also be used for filament winding. Examples of filament-wound products are tubes and storage tanks.

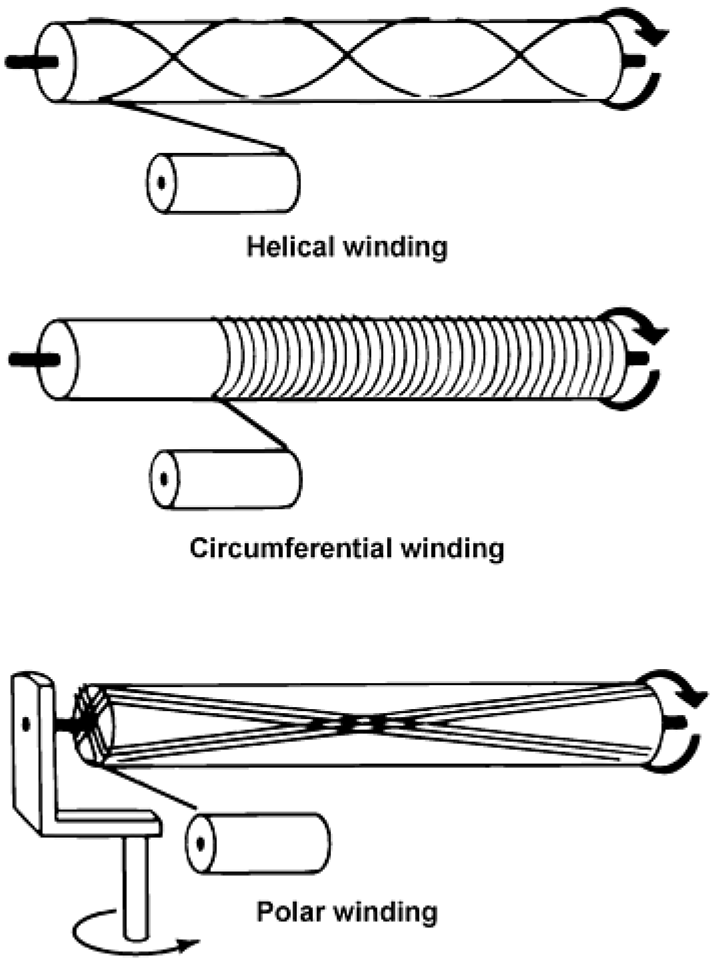

Fig. 2 Schematic representations of winding techniques

High-pressure laminates are made by stacking layers of resin-impregnated sheets (prepregs), then applying heat and pressure to bond the layers together. The pressures applied range from 8 to 14 MPa (1200 to 2000 psi).

In most laminated designs, the plies (layers) are arranged at a variety of angles. In high-performance applications, plies used in the laminated stack are oriented at fixed angles to the direction of major load. The most common fixed load angles are 0, 45, -45, and 90° to the major load axis (Fig. 3). By selecting the proper number of plies at each of these angles, composite properties and their anisotropies can be designed for strength, modulus, or even the degree of thermal expansion along each principal direction.

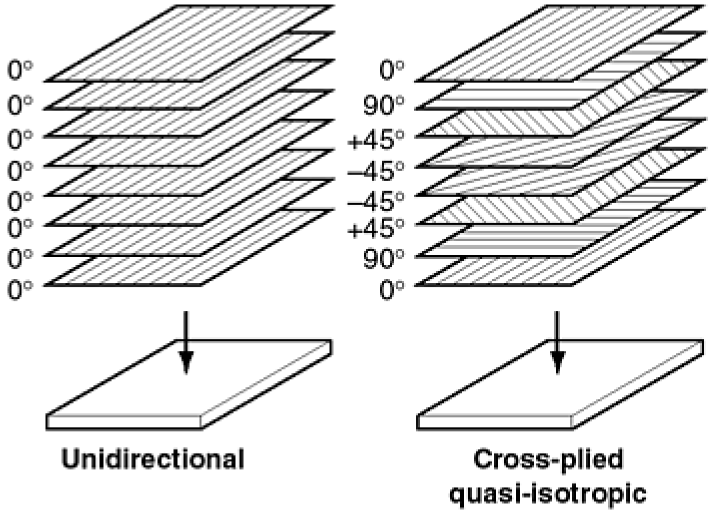

Fig. 3 Typical composite laminate configurations

In addition to making flat and curved laminated sheets, high-pressure laminating can be used to produce laminated tubing by winding the impregnated sheet under pressure on a mandrel, then curing the resin. Because of the high pressures used, the size of parts made by this method is limited by the sizes of available presses.

Compression molding, sometimes referred to as matched-metal molding, employs either bulk molding compound (BMC) or sheet molding compound (SMC). Bulk molding compound is a prepared mixture of thermosetting resin, chopper fibers (glass, carbon, or aramid, with lengths ranging from 3 to 50 mm, or $\frac{1}{8}$ to 2 in.), filler, catalyst, and other additives. It is supplied in bulk form or as extruded "rope." The required amount of the mixture is placed in a heated mold, which is then closed, subjected to pressure, and cured. Sheet molding is similar to bulk molding, but the reinforcement is longer glass fibers, 25 to 75 mm (1 to 3 in.), and the compound is supplied in sheet form. The sheet is first cut to a shape similar to that of the mold and is then pressed and heated in the mold for curing.

Preform molding involves spraying a mixture of chopped glass roving and weak binder on a pattern resembling the product. The preform is then placed in a heated metal mold and saturated by a mixture of resin, catalyst, fillers, and pigment. Curing then takes place under pressure. Cold-press molding is similar to preform molding, except that curing takes place at room temperature and under low mold pressure. This allows the use of inexpensive mold materials such as plastics and plaster. Preform molding gives more consistent and more attractive products than those produced by lay-up or spray-up processes.

Resin transfer molding (RTM) is a matched-mold process that uses low-cost molds. The reinforcement is laid up dry in the mold, and liquid-catalyzed resin is pumped in until the mold is filled and the pressure reaches about 170 kPa (25 psi). The process can be vacuum assisted (VARTM) to prevent trapped air pockets and to assist with the flow of resin. The curing time is a function of the resin and can vary from about 15 min to on the order of 1 h. This process is considered intermediate between spray-up and the faster pressure-molding methods. It is suitable for medium-volume production and can be used for manufacturing complex parts for automobile and truck bodies. Tailoring composites by placing extra reinforcement in highly stressed areas makes it possible to consolidate several smaller parts into one large structure, thus reducing assembly operations and cost.

Pultrusion is used for reinforced thermosetting plastics to make shapes similar to extruded shapes. The reinforcing fibers are immersed in a liquid-resin bath and are then pulled through a long heated die to cure the resin (Fig. 4). Rubber-faced rolls, which are shaped to the required form of the pultrusion, pull the cured and finished shape from the die. The pulling speed ranges from 50 to 5000 mm/min (2 to 200 in./min), depending on the resin compound, shape and thickness of the section, mold temperature, and mold length. The most commonly pultruded materials are glass-reinforced unsaturated polyester resins. Standard pultruded shapes are available in the form of:

- Solid bar of round, rectangular, and dogbone cross section
- Hollow shapes of round and rectangular cross section
- Structural shapes, such as channels and I-beams
- Sheet of flat and corrugated cross section

Epoxy resins can also be used in pultrusions, but they require longer curing time and do not release as cleanly from the dies.

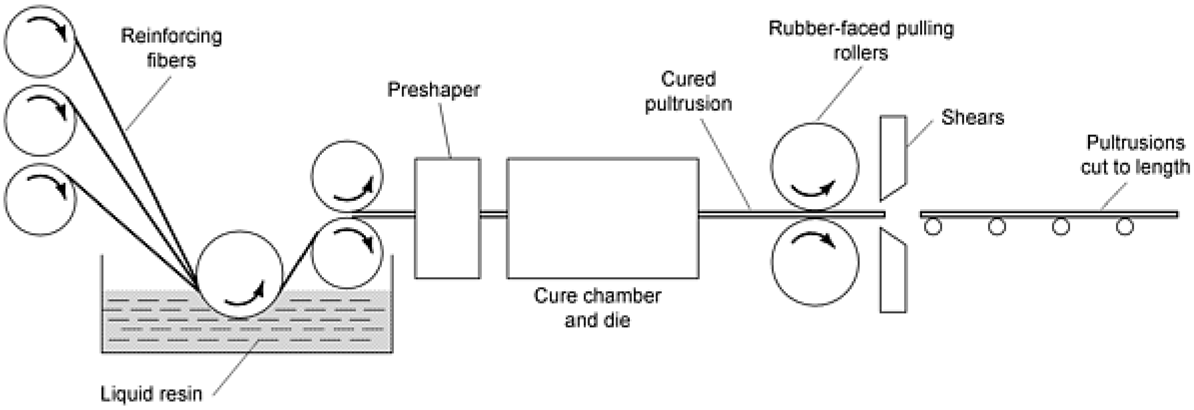

Fig. 4 Schematic of the pultrusion process for fabricating composite products

Design for Composite Manufacture

Anthony J. Vizzini, University of Maryland

Process Considerations

Independent of selections made prior to the design, many aspects of the manufacturing process are still unknown and are a function of the microscale and macroscale design of the component. The general composite manufacturing process can be subdivided into three separate stages. The first is preparation and involves handling the raw materials as well as mold fabrication and preparation. The second stage is the actual forming process. It is in this process that chemical reactions occur or the constituents are consolidated into the desired component. Finally, additional fabrication may be required such as trimming, machining, bonding, finishing, or coating.

Preparation

Two aspects of manufacturing that interact with the design are the handling qualities of the raw materials and characteristics of the mold. Prior to the manufacturing step, materials are available as individual constituents or in mixed form. As individual constituents, they are either combined prior to the manufacturing process or combined as a result of the process. Materials premixed such as preimpregnated fabrics and tapes, SMCs, and BMCs may be assembled prior to the manufacturing process.

Handling Qualities. *Tack* is the ability of the material to stick to itself and to other materials. A tacky material will stay in place once it is situated on a mold or on top of another layer. Thermoplastics with little tack may need to be held in place in the mold through the use of a local heat source such as a heat gun. Materials with too much tack increase the effort required by the operator to place the material in the correct position because errors in placement cannot be easily remedied. The degree of tack is influenced by room temperature, relative humidity, and dryness of the material. Tack affects the design by limiting the size of the individual ply that can be handled and the ability to place it in the part.

Although templates can be used for positioning individual plies, tacky materials must be placed accurately the first time, whereas low-tack materials may shift prior to consolidation resulting in a disturbance in the location of a ply.

Drape is the ability of the material (fiber or fabric, with or without resin) to conform to the shape of the mold. The greater the drape, the more contour that can be designed into the part. Therefore, drape limits the radius of curvature in any given direction. This is separate from the concern of laying a planar material on a doubly curved mold or the reverse problem of representing in two dimensions a three-dimensional surface without distortions. Typically, thermoplastic materials have little drape and thus are made to conform to the shape of the mold during the manufacturing process as is done in thermoforming. However, thermoplastic materials that have been cut into long, narrow strips and then loosely laid as a stretchable fabric do exhibit some degree of drape.

Because thermosets cure at any temperature, preimpregnated staged materials have a finite workable time out of storage, and resin wet-out systems, once mixed, have a finite pot life. Beyond these time limits, the mechanical properties of the composite structure decrease and handling of the constituents becomes difficult. Thus, the time to complete the assembly must be addressed in the design of the component. If intricate plies are required, then automation must be employed in cutting the individual plies. The size of the structure may be limited by how much material can be applied without significant degradation of mechanical properties. However, there are manufacturing processes and materials well suited for long assembly times. Many of the closed-mold processes, VARTM, or structural reaction injection molding (SRIM), when used with preforms can reduce the handling time of the resin. The dry reinforcement is placed in the desired orientation, and then the resin is introduced.

The ability to properly wet out the fibers, to consolidate individual layers, and to decrease void content is related to the viscosity of the resin. There is a trade-off between increased wet-out and handling characteristics. Low-viscosity resins tend to pool in resin-rich areas for large parts, resulting in a lack of uniformity in fiber volume. Resin systems must be tailored to provide low viscosity during winding processes or in flow periods of autoclave processes, but must be able to remain where placed within the structure during the process.

Tooling Considerations. The role of the tool or mold is to impart the shape to the composite part during the manufacturing process. Tool design is based on the requirements for the tool to maintain its shape during the manufacturing process and is a function of the processing temperature, applied loads, and curing time. In addition the number of replicates per tool affects its material of construction.

Here, consideration of the manufacturing process is very important. The geometry of the part is constrained by the ability to form the necessary tooling. Highly contoured surfaces will require a highly contoured tool. Making use of available geometries such as flats and tubes results in low-cost tooling. Complex tooling requires manufacturing the desired master model shape using a rigid medium such as wood. The mold is made from this machined master model shape or plug, often using composite materials.

One key aspect that must be incorporated into the design is the phenomenon referred to as *springback.* Because of differences in thermal expansion, residual stresses arise during the manufacturing process. When the part is removed from the tool, the part deforms to the state governed by the residual stress state. For example, springback results in a one or two degree change in an "L"-section and can be addressed by considering the residual stress state in the design of the tool. Also, dimensional stability (shrinkage) must be calculated and accommodated in the mold design.

Forming Processes

Because the manufacturing process is to be designed concurrently with the component, design guidelines are flexible. Manufacturing of a designed component is often only limited by the creativity of the engineer and the budget of the project. Although all conceivable parts currently cannot be made with composites, the constant stream of new products using composite materials attests to the ingenuity of manufacturing engineers.

In general, the manufacturing process can impose limitations on the microscale, such as the orientation of the reinforcement, and on the macroscale, such as the ability to form an integrated structure. Although an individual forming process has specific requirements on types of resins and reinforcements that can be used, the design considerations can be discussed among three areas. Laminated hand laid-up structures require extensive labor and tooling and thus are used only in those applications where the added performance can justify the relatively high costs. A second group of forming processes are those that make use of dry reinforcements in a semicontinuous or continuous fashion such as filament

winding, braiding, or pultrusion. The third group includes the closed-mold processes as discussed in the article "Effects of Composition, Processing, and Structure on Properties of Composites" in this Volume.

Preimpregnated Tapes and Fabrics. Laminated preimpregnated materials often offer the greatest mechanical properties. High specific strength and stiffness are important in weight-constrained structures within the aerospace industry. Preimpregnation provides a consistent product with a uniform distribution of reinforcement and resin with high fiber-volume fractions possible. Such laminated structures typically require an excessive amount of hand labor and autoclave processing, resulting in a relatively high cost of manufacturing. Nevertheless, proper design of a composite component can decrease the overall manufacturing costs.

In laminated structures, the orientation of each ply is a design variable. This increases the complexity of the design process, and thus ply angles are often limited. Several common approaches include allowing only orientations that are multiples of 15° or, more stringently, laminates made up entirely of 0, +45, -45, and 90° plies. These design strategies limit the orientations that are involved if hand lay-up is to be used. However, limitation of angles may not be necessary. Templates can be used to cut material with the desired orientations and to place the plies on the tool. A trained worker can just as easily lay a 15° ply as a 17° ply. However, if the design requires many plies (shape and orientation), then additional care must be taken to sort the individual plies and to ensure that each ply is laid down in the correct sequence. It is also important that the tolerance for a given angle is not greater than ±3°. However, variations between specified and as-manufactured orientation will always occur.

The cutting of plies can be automated to increase efficiency and quality. Techniques include water jets, lasers, reciprocating knife, and die cutting. Using these methods, intricate plies can be cut with repeatability with no limitation on orientation of the reinforcement. A water jet introduces moisture to the uncured composite and extended exposure needs to be avoided. Laser cutting results in a heat-affected zone and may alter the local mechanical properties.

The contour of the tool is of great concern when using preimpregnated tapes and fabrics. Wherever there is a double radius of curvature, flat materials cannot be used without stretching or overlap. The inverse problem is to take any shape with a compound curvature such as a hemisphere and flatten it without excessive straining of the surface (Fig. 5a). One can see that the initial planar material requires many discontinuities. Even if cutting is reduced to a minimum as in the cone in Fig. 5(b), the orientation about the structure cannot be prescribed. Thus, a requirement for all of the fibers in a layer of a cone to be in one direction is impossible. The orientation of fibers in structures with realistic surface contours is a continuum problem that the designer must be aware of.

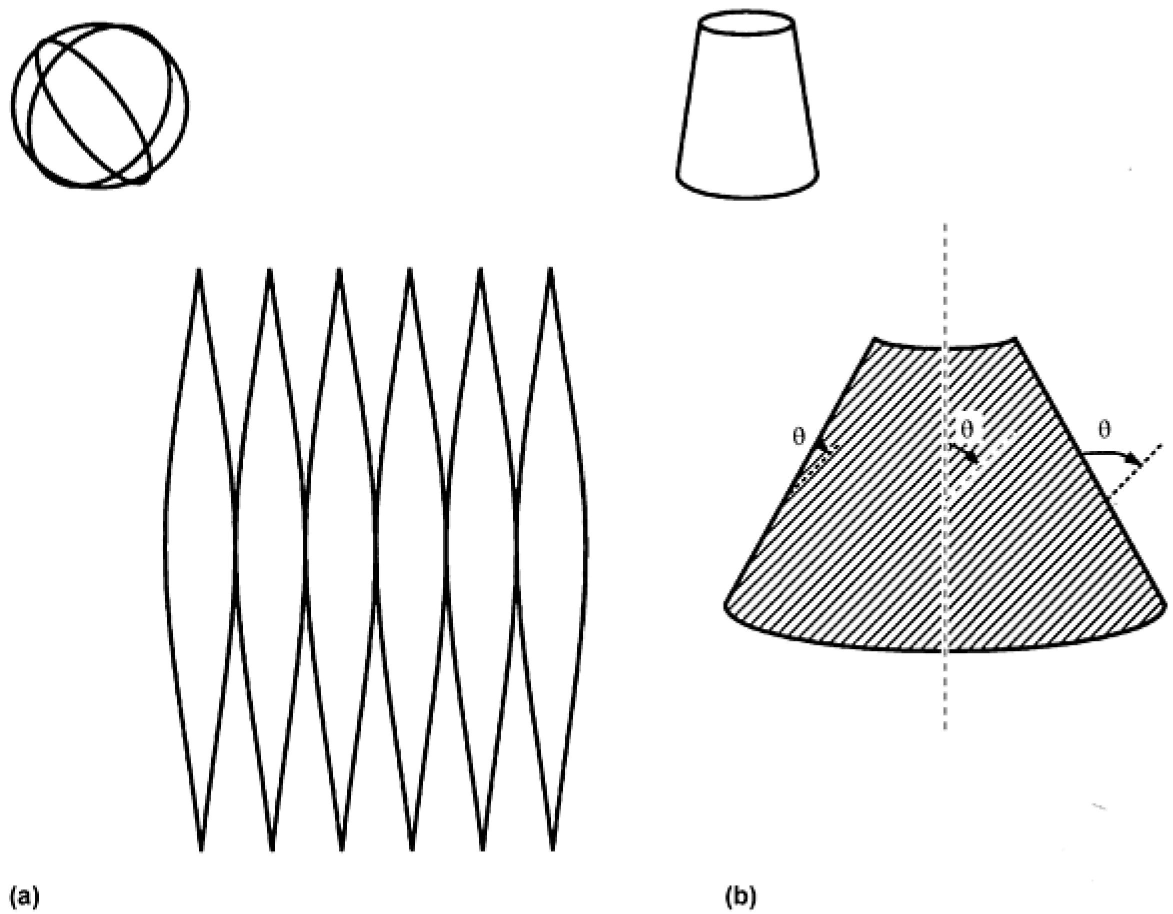

Fig. 5 Flattened contours (a) sphere and (b) truncated cone

Much of the above effort can be reduced by using tow placement. Individual tows or strips of preimpregnated material can be laid down using a multiaxis, multi-degree-of-freedom robot arm. The material is tacked to the tool by applying pressure through the head of the tow placing arm. If this head is heated or an external heat source such as a laser is used, then thermoplastics can be used. Individual strips can be placed on the tool in the desired orientation. This process removes the variations inherent in hand processing, although it requires extensive programming. Errors in orientations caused by the surface contour are limited by the width of the tow or strip being used.

Because most laminated structures are placed in a vacuum bag and additional autoclave pressure is applied, a major concern is maintaining the integrity of the bag during the forming process and proper transfer of the applied pressure to the part. In any concave portion of the part, the pressure bag can form a bridge if locally it is of inadequate size. Thus, insufficient consolidation will occur in that section. One approach that reduces this effect is a reusable silicone rubber bag. The bag is originally formed on the tool. Even if the bag conforms as it should, a fillet should still be allowed in a corner; however, the fiber volume in the fillet will be lower than the surrounding material. For example, if an I-beam is constructed by laying up two separate C-channels, placing them together, and applying additional plies on the flanges, a small resin rich pocket will form (Fig. 6a). To alleviate this resin-rich zone, additional material can be placed in that area to maintain the same fiber volume fraction (Fig. 6b). In some cases, this remedy cannot be applied. Because plies have discrete thicknesses, the thickness of a part is changed using terminating plies, resulting in a resin-rich area that cannot be filled. A possible remedy is the use of a preform of BMC partially staged that can be cured with overlaid flange plies.

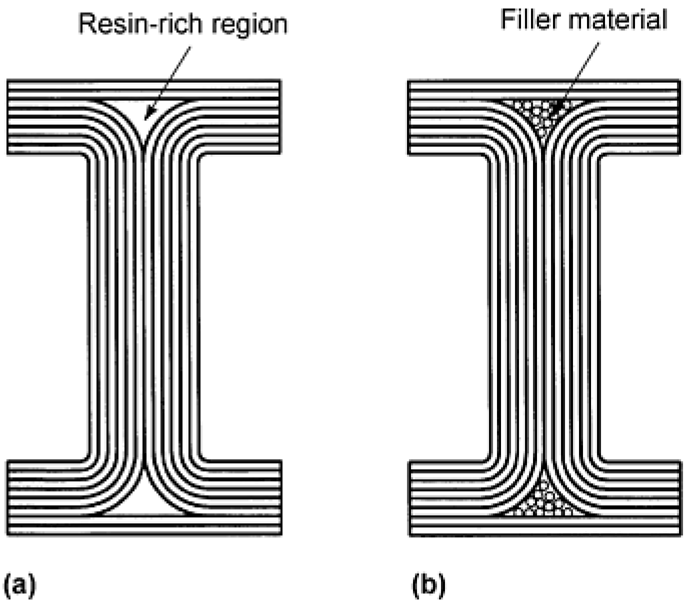

Fig. 6 Schematic of a C-channel with (a) a resin-rich region and (b) filler material to maintain fiber volume fraction

Dry Fibers and Broad Goods. One major disadvantage of the preimpregnated tapes and fabrics processes is that they are batch processes that involve significant hand labor or, in the case of tape layers, significant programming and capital investment. Mixing the reinforcement with the resin system in situ during the fabrication process allows for three-dimensional reinforcements or continuous processing while increasing material utilization.

In filament winding, fibers are drawn through a resin bath and wound on a rotating mandrel. This is the primary manufacturing method for cylindrical or spherical pressure vessels because the fibers are easily placed in the hoop direction. Low-cost constant cross-section components can be made using a filament winder with two degrees of freedom, the rotation of the mandrel and the translation of the payout eye. Increasing the number of degrees of freedom in the process increases its complexity as well as the complexity of parts that can be created. Additional payout eyes increase the speed of the process as well as introduce braiding. Variations to the winding process can include varying cross-sectional geometries, post-winding forming that can alter a convex outer surface to an I-beam shape as in Fig. 7, and inclusion of fixtures.

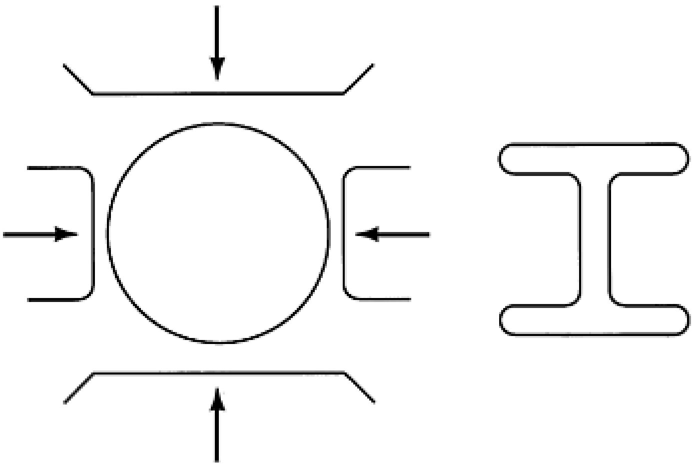

Fig. 7 Post-winding forming

One concern in filament winding is the angle of the fibers. Hoop (circumferential radial) winding involves laying fibers at nearly 90° with respect to the longitudinal axis of the mandrel. This results in high hoop strength. Helical (off-axis) or polar (axial, longitudinal) windings provide reinforcement along the length of the structure. As these fibers are wound, they have a tendency to slip. One exception is the geodesic path, which is a straight line on the flattened equivalent surface. As the part is formed, its thickness increases, thus changing the geometry of the process.

Pultrusion is used to produce indefinite-length constant cross-section components. Fibers, fabrics, and mats are pulled through a die with resin introduced at one end. The die is tapered to apply hydrostatic pressure to the resin resulting in fiber wet-out. An exothermic reaction can occur or heat is added to result in curing of the component. Design limitations include the need for sufficient reinforcement in the longitudinal (axial) direction to enable the process to be run. Annular cross sections or holes that increase the complexity and cost of the die, however, are preferred to post forming machining.

Molding Processes. The last set of forming processes involve forming with a closed mold. Such processes include matched-die molding, resin-transfer molding, and extrusion. These processes are used to fabricate parts in reasonable quantities within reasonable cycle times.

The constraints that are posed by the forming process are the methods by which the resin is introduced into the mold and how the chemical reaction is to occur. The flow characteristics are often non-Newtonian. Mold design is based on sophisticated software to locate entry and exit ports and to account for flow patterns, velocity shrinkage, and thermal expansion. Often the resin is curing as it is being introduced into the mold; thus its rheology is a nonlinear function of time. Clearly, there are limitations in the shape of the component. A high degree of compartmentalization of the mold increases the need for many entry ports.

Often dry reinforcement is placed in the mold before the resin is introduced. Fabrics, mats, and preforms of various cross sections and geometries are possible by employing the expertise of textile engineers.

Fabrication Processes

Once the consolidation process is completed, the component usually requires additional fabrication steps to complete. The part is trimmed, holes are drilled, the surface may be prepped and painted. In addition, several parts may be bonded to form a larger component or secondary bonding is performed to yield a sandwich structure. The design of the component must also specify these steps and must anticipate possible adverse effects.

Machining. The shape and form of a metallic structure is realized in the machining process. Composite structures are formed prior to being machined. Machining is necessary to facilitate mechanical joints, cut small parts from stock items, and remove excess material. To avoid damage, composites should not be machined using metal techniques that use cutting, tearing, or shaving tools. Thus, if a cavity is required, it should be formed in the consolidation process and not by machining unless it is a thick-walled shape or has a "strong-back" composite or metal liner bonded in the hole cavity.

Cured composite materials can be cut using a number of techniques including mechanical methods, water jet, or laser. Mechanical methods require an increase in tool speed, a decrease in the feed rate, and a cooling lubricant. Often carbide tip tooling is used; however, to prevent excessive damage or delamination to the composite structure, diamond-grit tooling should be used. Thus, the composite structure is machined using abrasives. Care must be taken to allow for particle removal and to prevent heating the part.

Water jets and lasers provide for a greater amount of complexity in cutting. Water jets can cut through a 25 mm thick structure at relatively fast feed rates (1.5 m/min) and can be used for intricate details. The starting point of the water jet must be away from the part edge because of the possibility of delamination. Lasers require no start-up location, but damage occurs because of local heating of the structure. This is especially true in low thermal conducting materials such as composites with glass reinforcement.

Because of the potential threat of damage during machining, designs should limit the amount of required postfabrication forming. Near-net-shape fabrication can result in a minimum amount of machining. Whereas holes can be drilled effectively, it is often better to incorporate a fixture into the component during its forming rather than to attach it through mechanical means later.

Bonding. The ability to reduce the number of parts in an assembly is a clear advantage of using composite materials. Yet if the manufacturing and design processes are developed independently of each other, this advantage will be severely

diminished. An illustrative example of the choices available is a stiffened plate. In Fig. 8(a), the plate is made in three separate steps. The skin is fabricated, the stiffener is fabricated, and a secondary bond is performed. Although the stiffener fabrication may make use of a high-yield low-cost method such as pultrusion, some cost benefit will be lost by performing the secondary bond. One alternative is to cocure the stiffener with the skin. Film adhesive that has a similar cure cycle as the resin can be used to increase the integrity of the bond line. In Fig. 8(b), the stiffener may or may not be precured. A second variation has the stiffener now integrated with the skin. In Fig. 8(c), the macroscale of the design has increased resulting in additional specifications on the microscale. Finally, the whole concept of skin/stiffener construction can be abandoned and either a foam-filled hat section (Fig. 8d) or a sandwich construction can be used.

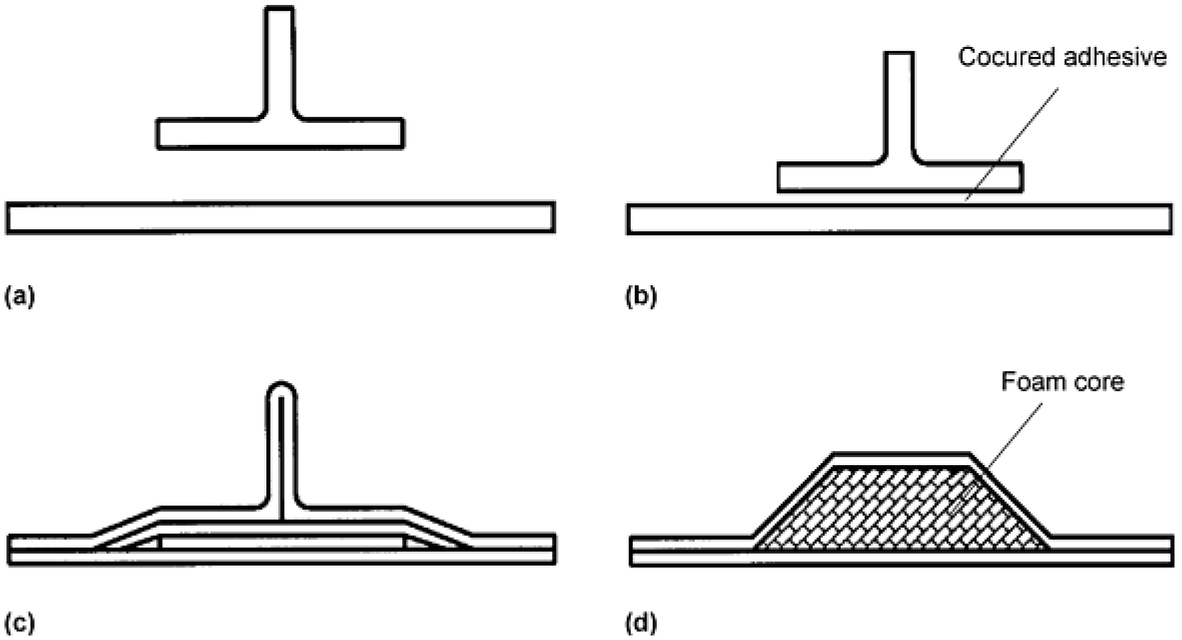

Fig. 8 Integration of stiffener and skin. (a) Mechanical/adhesive attachment. (b) Cocured. (c) Integrated lay-up. (d) Redesign

Again, if one approaches a composite structure with the same limitations imposed by metal construction the potential of the composite material is not achieved. For example, an aircraft fuselage is constructed using a thin skin stiffened by longerons along its length and hoop stiffeners about its circumference. The intersections of these stiffeners are at right angles out of fabrication necessity. This limitation is imposed primarily because the metal structure must be made in many pieces and assembled. The true design objective of flexural and torsional stiffness can be met more efficiently if the artificial constraint of right-angle stiffeners is removed.

Sandwich structures provide high bending stiffness at low weight. Various core materials are used such as balsa wood, aluminum or Nomex honeycomb, or syntactic closed-cell foams. The face sheets can be formed separately and bonded to the core, cocured with the core, or cured in separate steps layer by layer. Forming core to different contours requires additional fabrication. Foam and honeycomb cores can readily conform to flat and circular sections. Compound curvatures are more difficult to attempt. The minimum radius of curvature is determined by the core material. Lower density core materials tend to conform easily but may offer lower through-the-thickness stiffness and strength. The use of in-place foaming or scored foam boards allows complex curvature or shapes while maintaining structural integrity.

The manufacturing process determines the consolidation pressures seen by the face sheets during their forming process. If cured separately, then high pressures can be used. Secondary bonding then occurs at temperatures lower than the cure temperature of the face sheets and at significantly lower pressures so as not to compromise the core material. Curing face sheets on the core directly results in a slight dimpling if honeycomb cores are used. If a resin infusion method is being used, honeycomb cores must first be sealed.

When using sandwich structures, the edges must be closed out to allow for joining and to prevent water intrusion. Several techniques are used, and some require machining of the core. Solid cores such as foam and balsa wood can be readily cut

or sanded into the desired shape. Honeycomb cores require special cutting tools. The machined-out core is then backfilled with a resin/filler edging compound and cured.

Repair

An often overlooked aspect of manufacturing with composites is repair. Repair is necessary if the component is damaged during its manufacture or if a quality assurance check indicates that certain specifications are not met. The choice between repair or rejection depends on the ability to repair the structure effectively. This requires both access and proper procedures. Clearly, a proper design would anticipate likely damage events such as delicate areas being overstrained prior to final assembly or a tool drop on a composite surface. Poorly designed manufacturing processes yield a systematic flaw that may go undetected until the component is in the field.

General guidelines apply for composite repair as they do for repair of metallic structures. Convenient access should be provided. Thus there is a trade-off between fully integrated structures and structures that are assembled with mechanical fasteners. Composite repair requires significant surface preparation. The damaged material is first removed, and the surrounding good material is scarfed, chemically cleaned, and primed. A filler or partially staged or cured bonded preform and a surface patch of several plies of fabric/resin prepreg is applied to return the strength and stiffness, to restore the contour of the surface, or to prevent water intrusion. Application is accomplished using a portable heating and vacuum bag unit. The core of sandwich structures is replaced if it is damaged. This necessitates an additional bonding cycle.

Anthony J. Vizzini, University of Maryland

Conclusions

The scale of design of a composite structure is substantially broader than an equivalent metal structure. This in turn increases the difficulty in the design process and is partly attributable to some of the advantages of composites, notably the ability to tailor the microstructure of the component and to integrate individual components into a single structure. This additional complexity is compounded by the relative scarcity of individuals who have knowledge of or experience with such materials. Design of metallic structures is aided by an older and larger pool of readily available experience. Clearly, the manufacturing practices of today involving milling machines, lathes, and drill presses have been honed in the preceding decades. Advanced composite materials are relatively new materials that pose new challenges to engineers. Moreover, it is unlikely that the necessary expertise in materials, structures, and manufacturing will reside in a single individual. Even simple components may require a design team and consultants to cover adequately the many facets involved in the process.

A key point is the need to codesign the manufacturing process with the component. Failure to coordinate both activities will result in higher costs and poorer performance. Indeed, manufacturing may offer alternatives to the design that an engineer biased by his or her experience with metals may not contemplate. The emergence of composite tooling for composite components clearly indicates the inability of conventional materials to be formed in other than conventional shapes.

One drawback of using composite materials is the relative lack of guidelines to assist in the design for manufacturability. New applications result in new challenges with little or no previous experience on which to build. An exposition in composite materials (International Composites EXPO '97 in Nashville, TN) displayed many new products in major and emerging end-use markets. Examples included a front-end apron for passenger cars that replaces 44 steel parts at a 25% weight savings and a sheet molding compound cross-vehicle beam that consolidates 20 steel and plastic pieces with a 10% weight savings. Such examples indicate the advantages of integrating large structures through the use of composites.

Almost all processes can be improved once implemented by controlling key parameters that affect the occurrence and development of defects and damage. Temperatures and pressures can be monitored and controlled to reduce process variations, yet mechanical performance may not be as sensitive to the processing variables as it is to the process itself. Care must be taken not to simply make incremental progress along a given path for an old process, but to explore alternative manufacturing methods. New raw materials, new processing materials, new methods are continuously being

developed. The increased role of textile science due to the emergence of braided preforms is an example of how advantages can be seen by those who are willing to exploit both old and new technology in different areas.

Control of Residual Stresses

U. Chandra, Concurrent Technologies Corporation

Introduction

ALL THERMO-MECHANICAL manufacturing processes--such as forging, extrusion, casting, heat treatment, welding, coating, and machining--create residual stresses in industrial products. There are situations when such stresses can be beneficial and are intentionally created, for example, compressive stresses on the outer surface of a component subjected to fatigue loads, autofrettage in gun barrels, and prestressed pressure vessels; even bolted connections and prestressed concrete can be included in this category. In many other situations, however, the presence of residual stress is detrimental to the integrity of the product under service conditions. Examples in this category include: tensile stresses on the outer surface of a component subjected to fatigue loads, tensile stresses on the inner surface of an austenitic stainless steel pipe caused by welding leading to intergranular stress-corrosion cracking in boiling water reactors, interlaminar stresses in coatings leading to their spallation, premature yielding or fracture (especially in brittle materials), and part distortion or dimensional instability. The presence of residual stresses in a part is also known to affect its machinability. For these reasons, mechanical and manufacturing engineers have long been interested in understanding the source of such stresses, their control, and relief (Ref 1, 2, 3, and 4).

In the case of metallic products, the selection of material is generally dictated by functional requirements such as the ability of the product to withstand service loads, resistance to wear or corrosion, and so forth. It is rare that the magnitude and distribution of residual stresses is a matter of primary consideration while selecting the material to manufacture a metallic part. The issue facing the manufacturing engineer is to control the residual stresses in the product once the material (and often the manufacturing process) has already been selected. In the case of a composite or coated product, however, minimization of residual stresses is a prime consideration while selecting the constituent materials. This article primarily deals with metallic products.

A logical way to control residual stresses in a product should consist of the following steps:

1. Understanding the fundamental sources of stress generation
2. Identifying the parameters that can cause residual stresses in a particular manufacturing process
3. Understanding the relative significance of each one of these parameters
4. Experimenting with the most significant process parameters until a suitable combination is obtained that results in the desired magnitude and distribution of residual stresses

If the residual stresses in the product are still higher than acceptable, the only recourse left is the use of one of the various techniques of stress relief or the inducement of a stress pattern more favorable than the original.

The fundamental sources of residual stresses in a product can best be understood with the help of the disciplines of solid mechanics, heat transfer, and metallurgy, as discussed in the section "Fundamental Sources of Residual Stresses" in this article. The identification of process parameters comes from an engineer's knowledge of and experience with a particular manufacturing process. Finally, to understand the relative significance of each process parameter and to arrive at their optimal combination one can use either of two approaches: trial and error on the shop floor combined with a suitable method of stress measurements, or computer simulation, especially one based on the finite element method. Both of these approaches have some advantages and limitations. In general, computer simulation offers a more economical and efficient means of performing a parametric study. It also helps in understanding the behavior of the product at various intermediate stages of its manufacture. For example, in case of forging, it is possible to monitor stresses during the entire duration of the die motion, as well as after the die removal. Computer simulation also helps in monitoring other phenomena of interest, such as the flow of material during forging. However, the trial-and-error approach offers only one opportunity to see the effect of changing a process parameter, for example, after the die removal. On the other hand, trial and error requires less investment in personnel training and development of a material properties database. Also, the use of physical modeling in a laboratory coupled with residual-stress measurements is still needed to verify the results of computer simulation until full confidence in the accuracy of simulation code and personnel skill is attained.

Until recently, the trial-and-error approach has played a more prominent role in the control of residual stresses in industrial products, as compared to its simulation counterpart. However, in recent years, considerable progress has been made in computer simulation of several manufacturing processes, for example, casting, forging, quenching, and postweld heat treatment. In such processes, it is expected that computer simulation will soon be used routinely on the shop floor. Until then, a judicious combination of computer simulation and trial and error appears to be the most prudent approach to control the residual stresses. On the other hand, in the case of shot peening and some other processes, computer simulation is either not mature enough or is too uneconomical to be used as an alternative to trial and error, at least in the foreseeable future.

It is important to note that, before attaining its final shape, a product often undergoes a series of primary and secondary operations; for example, it may involve forging as the primary operation and quenching, aging, and machining as the secondary operations. Each of these operations affects the state of residual stresses in the part. Therefore, in order to control the residual stresses in a finished product, it appears logical to apply the aforementioned techniques (either trial and error or computer simulation) for each operation. In some cases (e.g., forging followed by quenching), it may be argued that the final manufacturing operation is mainly responsible for the state of residual stresses in the part and, hence, the effort to control them should focus on the final operation. However, this argument does not apply if the sequence of quenching and machining is considered. Hence, it should not be used as a general rule.

This article is an introduction to the subject of control of residual stresses. Its objectives are to:

- Introduce the various fundamental sources of residual stresses common to most manufacturing processes
- Explain the effect of material removal on residual stresses and distortions in a part
- Provide a summary of commonly used techniques of measuring residual stresses
- Provide a summary of the finite element method used for predicting residual stresses
- Demonstrate the application of the above to a few selected manufacturing processes

Because the number of manufacturing processes is too large, it is not possible to cover them all in a short article. Also, a listing of rules for control of residual stresses in various manufacturing processes is not attempted in this article, because an indiscriminate application of such rules without proper appreciation of the basic concepts could lead to adverse results.

It is hoped that the article provides some insight to a manufacturing engineer into the cause of residual stresses in a product and assists in identifying key process parameters responsible for such stresses. The article is also expected to assist in making a choice between the trial-and-error and computer-simulation approaches (or a combination of the two) for the control of residual stresses.

Control of Residual Stresses

U. Chandra, Concurrent Technologies Corporation

Fundamental Sources of Residual Stresses

In manufacturing processes, residual stresses are caused by a combination of some or all of the following fundamental sources:

- Inhomogeneous plastic deformation in different portions of the product due to mechanical loads or constraints
- Inhomogeneous plastic deformation due to thermal loads
- Volumetric changes and transformation plasticity during solid-state phase transformation
- A mismatch in the coefficients of thermal expansion

The mechanics related to these sources is explained in the remainder of this section. Also, an important concept related to the effect of material removal (e.g., a casting mold, a forging die, or the material removed during machining) on the magnitude and distribution of residual stresses in the workpiece is introduced.

Mechanical Loads. Generation of residual stresses due to mechanical loads can be understood by consideration of the example shown in Fig. 1 (Ref 5). It consists of an assembly of three bars, each 254 mm (10 in.) long with a cross section of 25.4 mm (1 in.) square. The bars are spaced 25.4 mm (1 in.) apart, center to center. The two outer bars are made of the same material with an elastic modulus of 207 GPa (30 × 10^6 psi), yield strength of 207 MPa (30 ksi), and plastic modulus of 41 GPa (6 × 10^6 psi). The middle bar has a higher yield strength of 414 MPa (60 ksi), but the same elastic and plastic moduli as the two outer bars. The upper ends of the three bars are fixed and not allowed to move in any degree of freedom; their lower ends are tied to a rigid but a weightless block. Also, the assembly carried a load *P* in the center, as shown in Fig. 1.

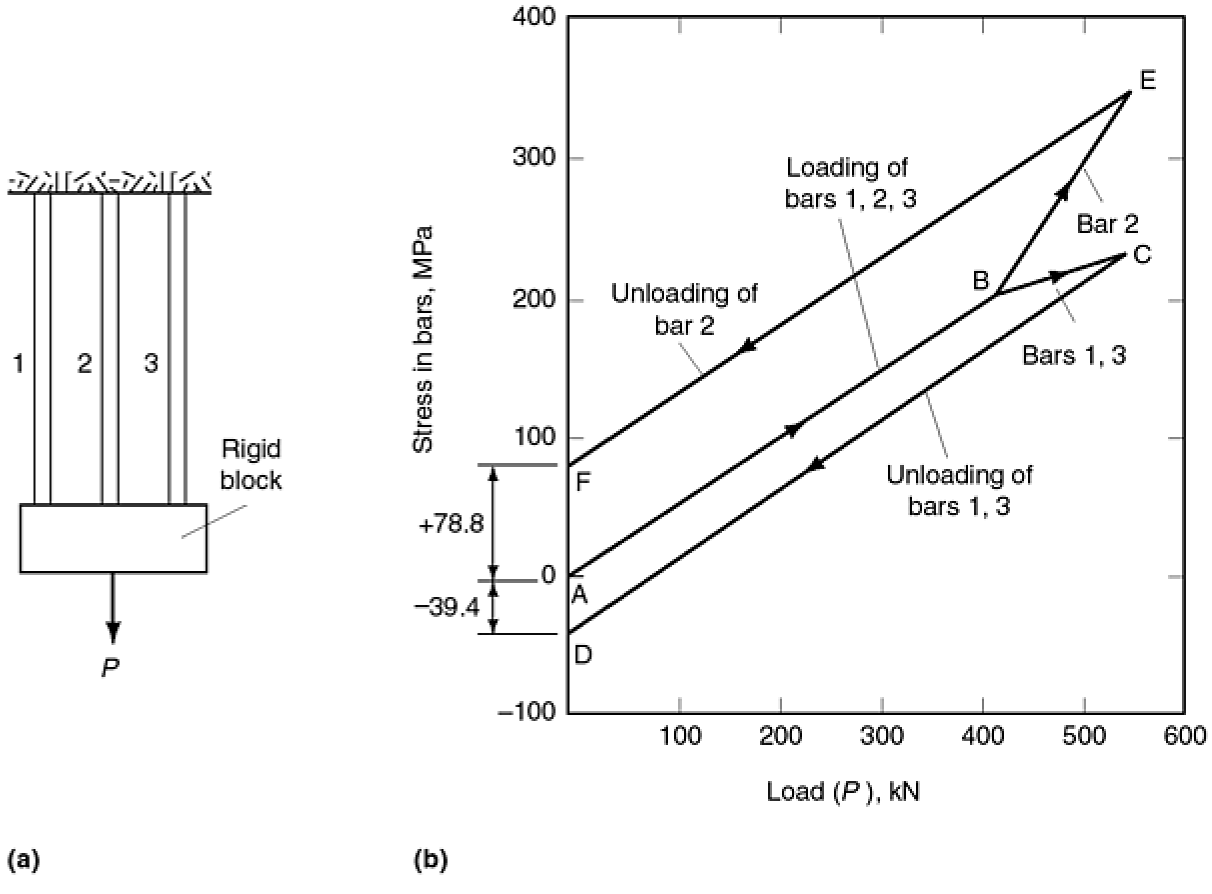

Fig. 1 Residual stresses caused by mechanical loads in an assembly of three bars. Source: Ref 5

Now consider two different loading histories. In the first case, the load *P* is gradually increased from 0 to 400 kN (90 kips), and then brought back to zero. When *P* is 400 kN (90 kips), each bar shares 133 kN (30 kips) and the stress in none of them exceeds the yield strength. On unloading, the original zero stress state in each bar is restored, and no residual stresses are introduced.

In the second case, *P* is increased from 0 to 534 kN (120 kips) and then brought back to zero. The entire history of stresses in the three bars is shown in Fig. 1(b). When *P* exceeds 400 kN (90 kips), the two outer bars deform plastically and, because of the reduced modulus, begin to share less load. The stress in the two outer bars follows the path ABCD, whereas that in the middle bar follows the path ABEF. It can be seen that when *P* is again zero (unloading), the stresses in the three bars do not go back to zero. Instead, the middle bar has a residual tensile stress of 78.8 MPa (11.4 ksi), and each of the two outer bars has a residual compressive stress of 39.4 MPa (5.7 ksi). Because there is no external load on the assembly, the residual stresses in the three bars are in self-equilibrium. A comparison of the two loading histories indicates that the presence of inhomogeneous plastic deformation in the three bars is responsible for the generation of residual stresses. Similarly, mechanical residual stresses occur in any component when the distribution of plastic deformation in the material is inhomogeneous, such as the surface deformation in shot-peening operation.

Thermal Loads. A similar three-bar model explaining the generation of residual stresses due to inhomogeneous plastic deformation caused by thermal loads is discussed by Masubuchi (Ref 6, presumably adopted from Ref 7). In this model, three carbon-steel bars of equal length and cross-sectional area are connected to two rigid blocks at their ends. The middle bar is heated to 593 °C (1100 °F) and then cooled to room temperature, while the two outer bars are kept at room temperature. Some of the details are not clearly explained in Ref 6, but the problem is very similar to the previous example. When the temperature in the middle bar is raised, the requirements of compatibility and equilibrium imply that a compressive stress be generated in the middle bar and tensile stresses in the two outer bars; the stress in each of the two outer bars being half of that in the middle bar. If the temperature in the middle bar is so high that its stress exceeds yield but in the two outer bars the stresses are still below yield, residual stresses will occur in the three bars when the temperature of the middle bar is brought back to room temperature (i.e., on unloading). Similarly, if the stresses in all three bars exceed yield but by different amounts, residual stresses will still occur when the temperature of the middle bar is brought back to room temperature. Indeed, this case is very similar to that of a cylinder immersed vertically in a quenchant where, during the initial stages of quenching, the temperature in the outer layer is much lower than that in the inner core.

The three-bar model can be further utilized to explain the generation of residual stresses due to the mismatch in coefficients of thermal expansion. For example, suppose the two outer bars represent the layers of matrix in a composite lamina and the inner bar represents a layer of fibers. The coefficient of thermal expansion of the two outer bars is equal but, in general, different from that of the middle bar. It is assumed that the initial temperature of all the three bars is equal, which corresponds to a certain processing temperature much higher than room temperature. When the assembly is brought to room temperature, the requirements of compatibility and equilibrium will be satisfied if a system of forces (residual stresses) is established such that the sum of the forces in the two outer bars is equal and opposite to that in the middle bar. In this case, the presence of unequal plastic deformation is not a prerequisite for the generation of residual stresses. This explains why, while selecting the constituent materials for a composite or for a coating, the designers try to minimize the mismatch between their coefficients of thermal expansion.

Solid-State Transformation. In quenching, welding, and casting processes, many metals such as steels undergo one or more solid-state transformations. These transformations are accompanied by a release of latent heat, a change in volume, and a pseudoplasticity effect (transformation plasticity). All of these affect the state of residual stresses in the part. The release of latent heat during solid-state transformation is similar to that during the liquid-to-solid transformation, albeit of a smaller amount. The change (increase) in volume occurs due to the difference in mass densities of the parent phase (e.g., austenite) and the decomposed phases (pearlite, ferrite, bainite, and martensite). In steels, the volumetric change due to phase transformation is in contrast to the normal contraction or shrinkage during cooling (Ref 8).

A simple example of transformation plasticity is shown in Fig. 2, which is based on the results of a constrained dilatometry experiment (Ref 9). The figure shows that during cooling in the phase transformation regime, the presence of even a very low stress may result in residual plastic strains. Two widely accepted mechanisms for transformation plasticity were developed by Greenwood and Johnson (Ref 10) and Magee (Ref 11). According to the former, the difference in volume between two coexisting phases in the presence of an external load generates microscopic plasticity in the weaker phase. This leads to macroscopic plastic flow, even if the external load is insufficient to cause plasticity on its own. According to the Magee mechanism, if martensite transformation occurs under an external load, martensitic plates are formed with a preferred orientation affecting the overall shape of the body.

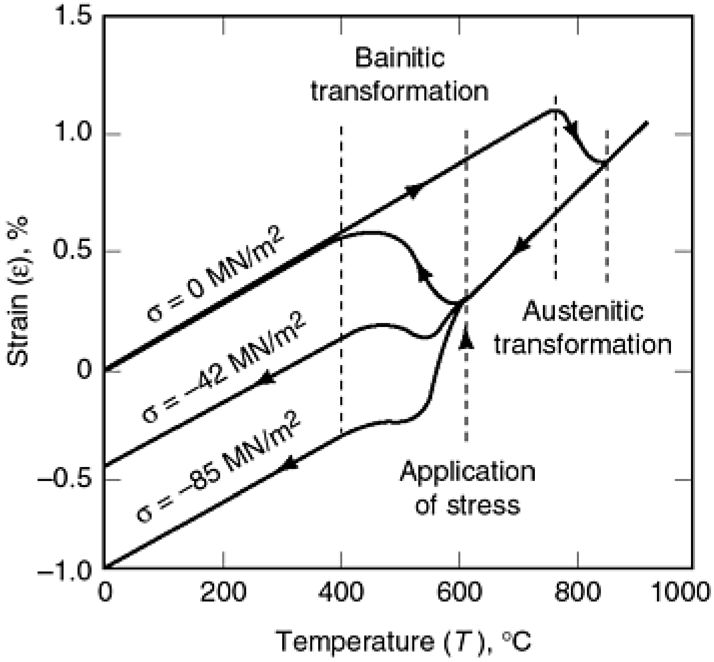

Fig. 2 Transformation plasticity. Source: Ref 9

Material Removal. A fact that is often overlooked in discussing residual stresses caused by various manufacturing processes is the effect of material removal on the state of stresses in the product. Consider, for example, that a casting mold must be finally broken and removed, or a forging die must be retracted. Likewise, in making a machined part some of the material has to be removed. All of these operations change the state of stress in the part. In order to fully understand this concept, three examples discussed in Ref 5 should be considered.

The first example entails an assembly of two concentric springs of slightly different lengths, L_i and L_o, as shown in Fig. 3(a); the subscripts i and o refer to inner and outer springs, respectively. The bottom ends of the two springs are fixed. Then, the upper ends are tied to a rigid block that is free to move only in the vertical direction. The two springs adopt a compromise length, L, which is in between L_i and L_o, as shown in Fig. 3(b). As a result, the two springs develop equal and opposite forces: compressive in the longer inner spring and tensile in the outer shorter spring. The assembly of the two springs may be viewed as analogous to the assembly of a cast part and its mold or to the assembly of the forged part and the die, or to a machined part before some portion of it is removed. Then, the removal of the outer spring becomes analogous to removal of material during machining (Ref 5, 12), of the casting mold (Ref 13, 14, 15, and 16), or of the forging die (Ref 17). Two cases are considered. In the first case, the stresses in both springs are assumed to be within their elastic limits. When the outer spring is removed, the force acting on it is transferred to the inner spring in order to satisfy equilibrium and the inner spring returns to its original length. In the second case, it is assumed that the inner spring has undergone a certain amount of plastic deformation. When the outer spring is removed, the inner spring does not return to its original length, L_i. In either case, because the two springs and, therefore, the forces, are concentric, the residual stress in the inner spring becomes zero when the outer spring is removed.

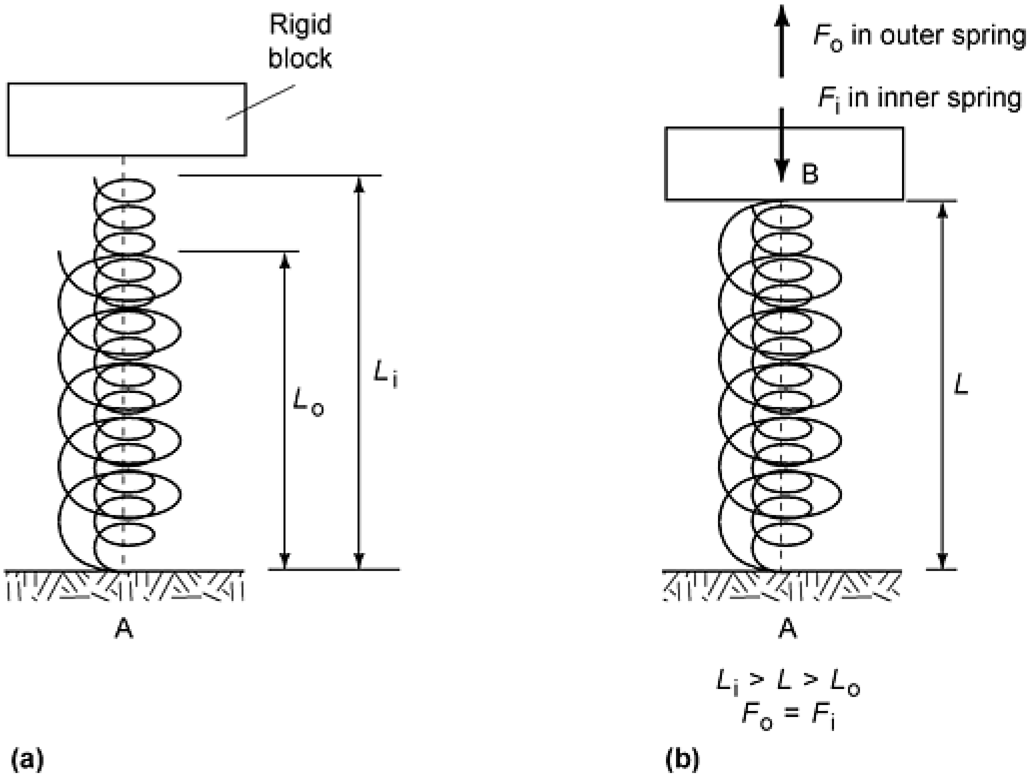

Fig. 3 Residual stresses in an assembly of two springs with unequal initial lengths. Source: Ref 5

For the second example, reconsider the three-bar model from the section "Mechanical Loads" in this article. After creating residual stresses in the three bars by loading and unloading the assembly, bar 3 is removed, by (for example) machining. As shown in Fig. 4(a) and 4(b), a redistribution of stresses in the remaining two bars takes place. The resultant stresses at the centroids of the two bars become -14.8 MPa (-2.14 ksi) in bar 1, and 14.8 MPa (2.14 ksi) in bar 2. Also, the assembly rotates (distorts) by an angle of 4.3×10^{-3} radians.

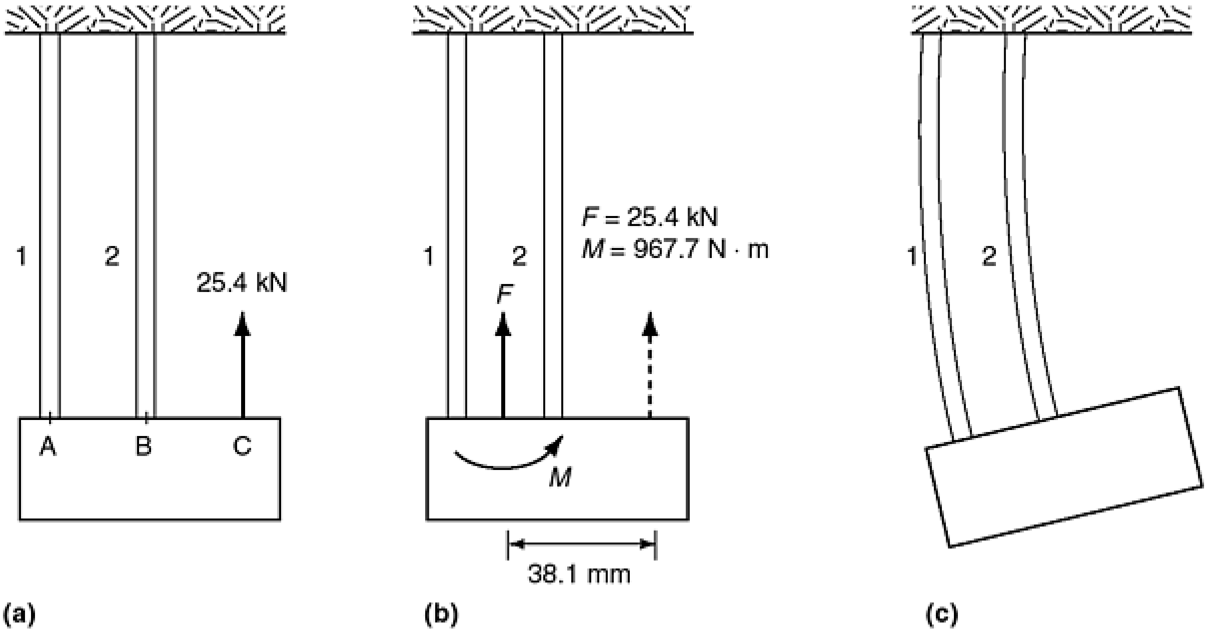

Fig. 4 Effect of asymmetric material removal in the three-bar model of Fig. 1. Source: Ref 5

The third example in Ref 5 is of a thick-walled cylinder with an internal diameter of 101.6 mm (4 in.) and an outer diameter of 203.2 mm (8 in.) as shown in Fig. 5(a). Both ends of the cylinder are restrained axially, and the cylinder is subjected to an internal pressure. A 25.4 mm (1 in.) thick (along the axis) slice of the cylinder is analyzed by subdividing it into 10 equal finite elements (5.08 mm, or 0.2 in., thick each) in the radial direction (Fig. 5b). The residual stresses are created by increasing the pressure from zero to 345 MPa (50 ksi), and then back to zero. The elements 1 and 2 are removed successively. The variation of the three stress components along the radius is shown in Fig. 6, before material removal (i.e., the residual stresses) and after removing the two layers. It may be noted that in an overall sense, the level of residual stresses goes down as the material is removed. However, this is not necessarily true in a local sense. Consider, for example, the circumferential stress at the centroids of elements 3 and 4 in Fig. 6(b); it increases as the material is removed.

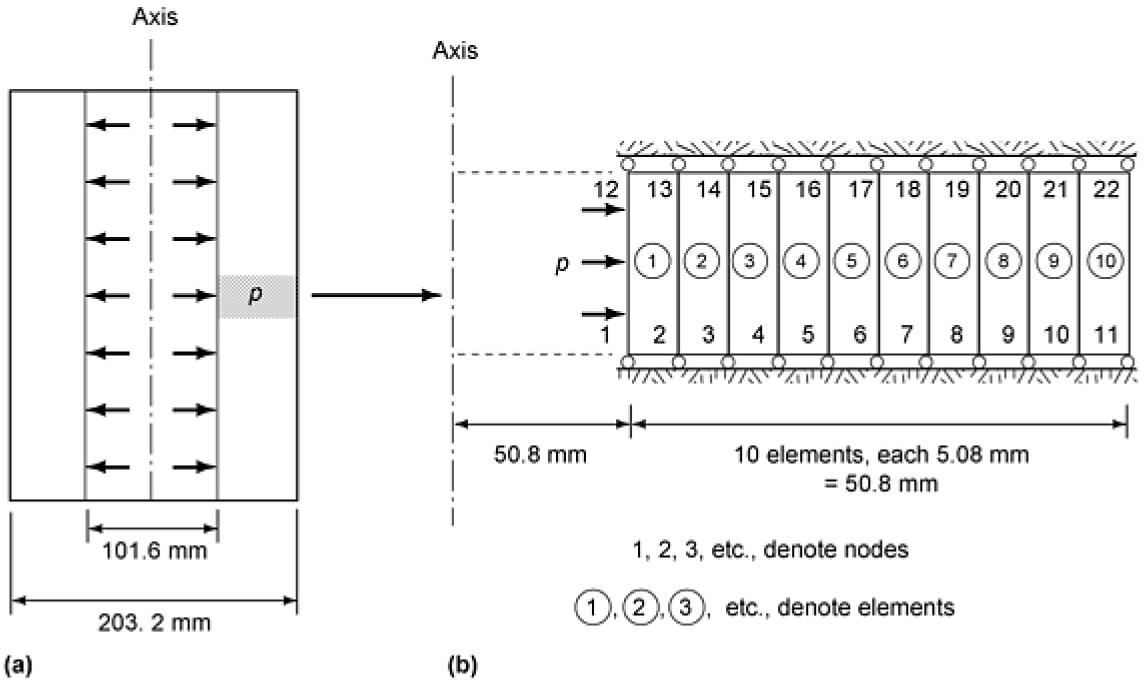

Fig. 5 Cylinder with internal pressure and its finite element mesh. Source: Ref 5

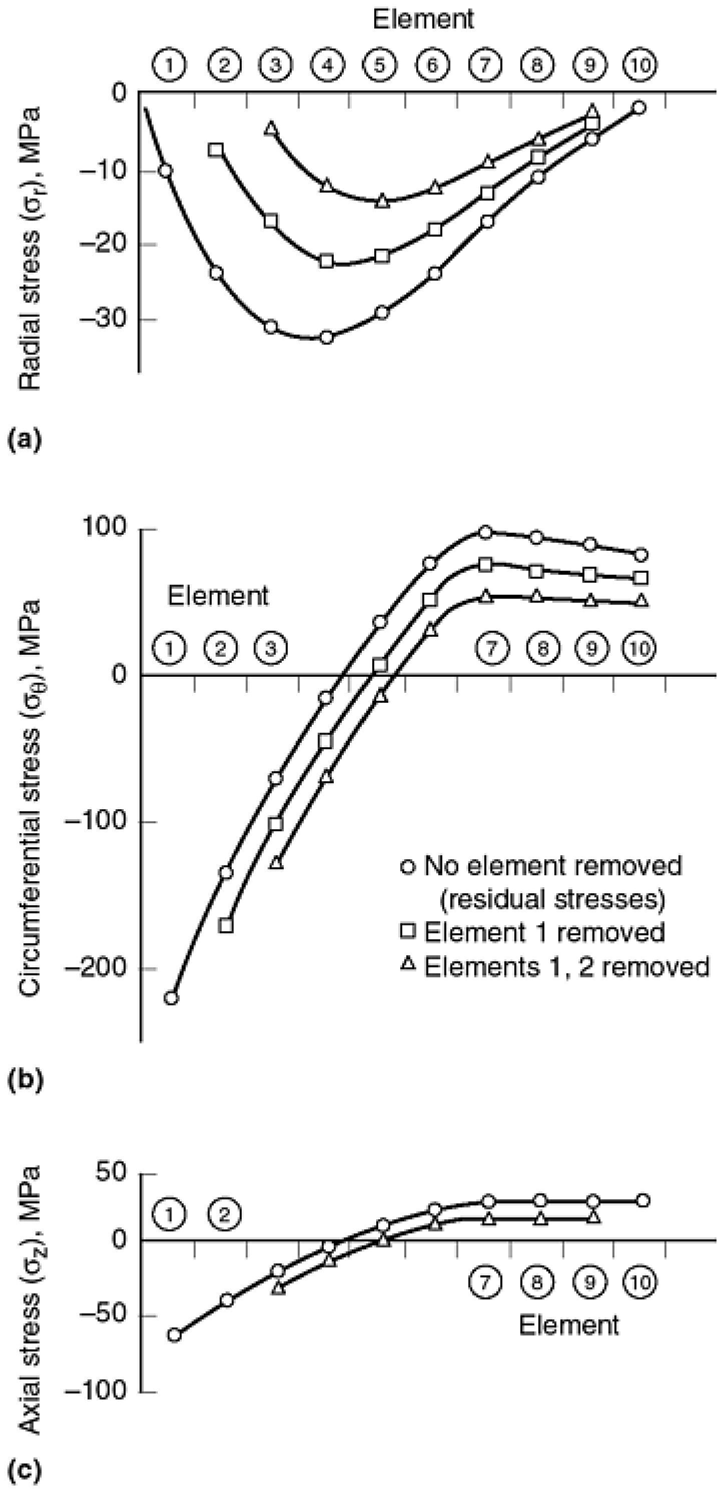

Fig. 6 Effect of removing layers of elements of material from the inside of the cylinder. Source: Ref 5

Important conclusions from the three examples discussed above can be summarized as follows:

- When the material removal is symmetric with respect to the stress distribution (Fig. 3), the residual stresses in the remainder of the assembly or part are very small or even zero.
- When the material removal is not symmetric with respect to the stress distribution (Fig. 4, 6), the residual stresses in the remainder of the assembly or part are not necessarily small.
- Material removal may result in an increase in stresses at some locations of the assembly or the part (Fig.

6).

Control of Residual Stresses

U. Chandra, Concurrent Technologies Corporation

Computer Prediction of Residual Stresses

In recent years, the finite element method has become the preeminent method for computer prediction of residual stresses caused by various manufacturing processes. A transient, nonlinear, thermomechanical analysis software is generally employed for that purpose. Some of the mathematics that form the basis of such software is common for all manufacturing processes. Such common mathematics is summarized by this section. However, because every process is unique, some mathematical requirements are, in turn, dependent on the process. Also, for the simulation of certain processes a sequential thermomechanical analysis is adequate, whereas for others a coupled analysis may be preferred or even essential. Such subtleties are pointed out later when individual processes are discussed.

Ignoring convection, the following conduction heat-transfer equation is solved with appropriate initial and boundary conditions:

$$\nabla \cdot (k\nabla T) + \dot{Q}_c = \rho C_p \frac{\partial T}{\partial t} \quad \textbf{(Eq 1)}$$

where T is the temperature at an arbitrary location in the workpiece at time t, k is the thermal conductivity of the material, $\dot{Q}_c$ is the rate of heat generated per unit volume, ρ is the density, C_p is the specific heat, and ∇ is the differential operator; all material properties are assumed to vary with temperature. The term $\dot{Q}_c$ accounts for the release of latent heat during liquid-to-solid transformation in casting and welding processes or during solid-state phase transformation in quenching, welding, or casting processes. It also accounts for the heat of plastic deformation in forging and other bulk deformation processes. The initial and boundary conditions are process dependent. Details of converting Eq 1 into its finite element form and of numerical solution are available in a number of technical papers and textbooks and are not repeated here. For a general treatment of the subject, the reader is referred to Ref 18, 19, 20, and 21.

The transient temperatures computed above are used as loading for the subsequent transient stress/displacement analysis. Using the incremental theory, the total strain increment $\{\Delta\varepsilon\}$ at time t can be divided into various components (Ref 22, 23, 24, 25, and 26):

$$\{\Delta\varepsilon\} = \{\Delta\varepsilon^e\} + \{\Delta\varepsilon^t\} + \{\Delta\varepsilon^p\} + \{\Delta\varepsilon^{cr}\} + \{\Delta\varepsilon^v\} + \{\Delta\varepsilon^{tr}\} \quad \textbf{(Eq 2)}$$

where superscripts e, t, p, cr, v, and tr refer to elastic, thermal, plastic, creep, volumetric change, and transformation plasticity components, respectively. The first three strain terms are needed in the simulation of every manufacturing process discussed here, whereas the use of the other three terms is dependent on the process and are pointed out as appropriate. Also, mathematical details for the first four strain terms are discussed in most standard references (Ref 22, 23), whereas the details for the last two terms are discussed often in the context of the simulation of quenching and welding processes (Ref 24, 25, 26).

In forging and other large deformation processes, the term $\dot{Q}_c$ in Eq 1 represents the heat of plastic deformation and leads to a coupling between Eq 1 and 2.

At present, no single computer code is capable of predicting residual stresses caused by all manufacturing processes. However, several general-purpose finite element codes are capable of predicting these stresses to a reasonable degree of accuracy for at least some of the manufacturing processes (Ref 27, 28, 29). In addition, some of these codes permit customized enhancements leading to more reliable results for a specific process. Before attempting to predict residual stresses due to a manufacturing process, it is advisable to compare the capabilities of two or three leading codes and use the one most suited for the simulation of the process in consideration. Examples of such comparisons are given in Ref 12 and 13 for forging, quenching, and casting processes. It must be noted that, due to continuous enhancement in these codes, it is always advisable to compare the capabilities of their latest versions.

Control of Residual Stresses

U. Chandra, Concurrent Technologies Corporation

Measurement of Residual Stresses

It is generally not possible to measure residual stresses in a product during its manufacture; instead, they are measured after the manufacturing process is complete. Smith et al. (Ref 30) have divided the residual stress measurement methods into two broad categories: mechanical and physical. The mechanical category includes the stress-relaxation methods of layer removal, cutting, hole drilling, and trepanning, whereas the physical category includes x-ray diffraction (XRD), neutron diffraction, acoustic, and magnetic. The layer-removal technique as originally proposed by Mesnager and Sachs (Ref 4) is only applicable to simple geometries such as a cylinder with no stress variation along its axis or circumference, or to a plate with no variation along its length or width. Thus, whereas it could be used to measure quench-induced residual stresses in a cylinder or a plate, it is not suitable for measuring complex stress patterns such as those caused by welding. The layer removal and cutting techniques, however, have been applied to pipe welds in combination with conventional strain gages and XRD measurements. The layer-removal technique is also used to measure residual stresses in coatings.

Hole-drilling and trepanning techniques can be used in situations where the stress variation is nonuniform, but they are generally restricted to stress levels of less than one-third of the material yield strength. Also, these two techniques can be unreliable in areas of steep stress gradients and require extreme care while drilling a hole or ring in terms of its alignment as well as the heat and stress generation during drilling (Ref 31). For such reasons, and others, these two techniques have found little application in the measurement of weld-induced residual stresses.

Of the methods in the physical category, XRD is probably the most widely used method, the neutron diffraction method being relatively new. These two methods measure changes in the dimensions of the lattice of the crystals, and from these measurements the components of strains and stress are computed. The XRD technique has undergone many improvements in recent years. With the development of small portable x-ray diffractometers, the technique can be used for on-site measurement of residual stresses. It should be noted, however, that this technique is capable of measuring strains in only a shallow layer (approximately 0.0127 mm, or 0.0005 in., thick) at the specimen surface. To measure subsurface residual stresses in a workpiece, thin layers of materials are successively removed and XRD measurements are

made at each exposed layer. For reasons discussed in the section "Material Removal" in this article, the measurements at an inner layer should be corrected to account for the material removed in all the previous layers. Reference 32 gives analytical expressions for such corrections in cases of simple geometries and stress distributions. For more complex cases, it still remains difficult to determine subsurface residual stresses accurately.

In contrast to the x-rays, neutrons can penetrate deeper into the metals. For example, in iron the relative depth of penetration at the 50% absorption thickness is about 2000 times greater for neutrons than for x-rays. Only a few materials, such as cadmium and boron, absorb neutrons strongly. However, to gain the advantage of greater penetration of neutrons requires the component to be transported to a high flux neutron source (Ref 30), which limits the use of the technique.

Control of Residual Stresses

U. Chandra, Concurrent Technologies Corporation

Residual Stresses Caused by Various Manufacturing Processes

Casting. In the past, little attention has been paid to the control of residual stresses in casting; much of the interest was focused on the prediction and control of porosity, misruns, and segregation. A review of the transactions of the American Foundrymen's Society or of earlier textbooks on casting (e.g., Ref 33) reveals practically no information on the subject; even the *ASM Handbook* on casting (Ref 34) provides little insight. In a recent book, Campbell (Ref 35) has included a brief discussion of residual stresses summarizing the work done by Dodd (Ref 36) with simple sand-mold castings. Dodd studied the effect of two process parameters: mold strength, by changing water content of sand or by ramming to different levels, and casting temperature. The conclusions of these costly experiments could have been more economically and easily arrived at by using the basic concepts discussed in the section "Fundamental Sources of Residual Stresses" and further amplified in the following paragraphs.

When a casting is still in its mold, the stresses are caused by a combination of the mechanical constraints imposed by the mold, thermal gradients, and solid-state phase transformation. Also, creep at elevated temperature affects these stresses. Finally, when the casting is taken out of its mold, it experiences springback that modifies the residual stresses.

As discussed in Ref 13, 14, 15, and 16, the computer prediction of residual stresses in castings requires a software that is capable of performing coupled transient nonlinear thermomechanical analysis (see the section "Computer Prediction of Residual Stresses" in this article). In addition, it should be able to account for the following:

- Release of latent heat during liquid-to-solid transformation, that is, in the mushy region
- Mechanical behavior of the cast metal in the mushy region
- Transfer of heat and forces at the mold-metal interface
- Creep at elevated temperatures under condition of varying stress
- Enclosure radiation at the mold surface to model the investment-casting process
- Mold withdrawal to model directional solidification

- Mold (material) removal

The author and his coworkers have recently modified a commercial finite element code and have analyzed simple sand-mold castings (Ref 15, 16). Computer simulation of these castings indicates that: (1) for an accurate prediction of transient and residual stresses, consideration of creep is important; creep is also found to make the stress distribution more uniform; and (2) just prior to mold removal the stresses in the casting can be extremely high, but after the mold removal they become very small (owing to the springback discussed in the section "Material Removal") except in the areas of stress concentration. The residual stresses after the mold removal will not necessarily be small if the casting is complex and the mold removal is asymmetric with respect to the stress distribution. Also, small variations in mold rigidity are not found to have any noticeable effect on residual stresses, which confirms the observations based on trial and error using green-sand molds with various water contents (Ref 35).

Although very little work is published thus far on the subject of control of residual stresses in castings, finite element simulation methodology is now sufficiently advanced to enable the study of the effect of various process and design parameters on the residual stresses in castings, for example, superheat, stiffness and design of the mold, design of the feeding system and risers, and the design of the part itself. Also, residual stresses caused by different casting practices such as sand-mold, permanent-mold, investment casting, and so forth, can be determined. As the manufacturers and end-users of cast products become more aware of the status and benefits of the computer-simulation methodology, it can be expected to play a very important role in controlling residual stresses in complex industrial castings. At present, the biggest limiting factor in the use of simulation is the lack of thermophysical and mechanical properties data for the cast metal and the mold materials.

Forging. As with the casting process, little attention has been paid in the past to the control of residual stresses caused by forging; most of the interest was in predicting the filling and the direction of material flow. Now, due to recent advances in computer-simulation techniques, it is possible to predict and control the residual stresses in forged parts.

Large plastic flow of the workpiece material is inherent in the forging process. The material flow is influenced by a number of factors including the die shape and material, forging temperature, die speed, and lubrication at the die/workpiece interface. Therefore, finite element simulation software used to predict and control residual stresses in the part should be capable of accounting for these factors. Because a significant amount of energy is dissipated during forging in the form of heat due to plastic deformation, a coupled thermomechanical analysis becomes necessary especially for nonisothermal forging. Other factors contributing to the complexity of the finite element simulation of this class of problems are: temperature-dependent thermal and mechanical properties of the materials (especially for a nonisothermal forging); the choice of solution algorithm and remeshing due to large plastic deformation in the workpiece; and mathematical treatment of the die/workpiece interface that includes heat transfer, lubrication, and contact. The last two terms in Eq 2 need not be considered in the simulation of the forging process.

Finite element simulation of the forging process with simple geometries and of a two-dimensional idealization of the thread-rolling process (Ref 17) showed that, although the stresses in the workpiece are high during the deformation stage, the stresses after retraction of the die (residual stresses) are no longer high except in the regions of stress concentration. Again, similar to the simulation of the casting processes, it is premature to generalize this conclusion but it is clear that the technique of computer simulation of forging and many other bulk deformation processes has advanced to a stage where it can assist in controlling the residual stresses in the part by performing a detailed parametric study with much less investment of time and capital than trial and error on the shop floor.

Quenching involves heating of the workpiece to the heat treatment temperature followed by rapid cooling in a quenchant (e.g., air, water, oil, or salt bath) in order to impart the desired metallurgical and mechanical properties. The choice of a quench medium is the key element; it should be such that it removes the heat fast enough to produce the desired microstructure, but not too fast to cause transient and residual stresses of excessive magnitude or of an adverse nature (e.g., tensile instead of compressive). The heat removal characteristic of a quenchant is known to be affected by a number of factors including the size, shape, orientation of the workpiece (even for simple shapes such as plates and cylinders, the heat removal is different at the bottom, top, and side surfaces); the use of trays and fixtures to hold the workpiece in the quenchant; composition of the quenchant; size of the pool and its stirring, and so forth (Ref 37, 38, 39). Additional difficulties arise when, due to economic reasons, quenching is performed in a batch process.

In the past, using trial and error, shop-floor personnel have come up with some interesting strategies to control the residual stresses (and warpage), for example, air delay or an intentional delay while transporting the workpiece from the

heating furnace to the quenchant, and time quenching or performing the quenching operation in two steps. In the first step, the part is quenched in a medium such as a salt bath until the part has cooled below the nose of time-temperature transformation curve, followed by quenching in second medium such as air to slow the cooling rate. Obviously, perfecting the quenching operation by trial and error can be an extremely time-consuming task.

At first glance, computer simulation of the quenching process may appear to be simple. It involves an uncoupled transient nonlinear small deformation thermomechanical analysis (as outlined in the section "Computer Prediction of Residual Stresses" in this article), with due consideration to solid-state transformation effects (Ref 9, 24, 25); creep is generally ignored. However, the major difficulty lies (for reasons discussed in the preceding paragraph) in a lack of knowledge of the heat removal characteristic of various quenchants, which is mathematically represented as the convective heat transfer coefficient at the outer boundary of the workpiece. Other difficulties arise due to the lack of thermophysical and mechanical properties of the workpiece material at elevated temperatures. Still, at least in the United States, major aircraft engine manufacturers and their forging vendors have been using computer simulation to control quench-related cracking and residual stresses for some time. One such example involving a turbine disk is discussed in Ref 40. The reported work was performed without the benefit of sophisticated simulation software that could account for solid-state transformation effects. For proprietary reasons, few such cases are published in the open literature.

Machining. Many complex parts in aerospace and other key industries are made by machining forgings, castings, bars, or plates to their net shapes. The presence of residual stresses in the workpiece affects its machinability and, on the other hand, the machining process also creates residual stresses and undesired distortions in the part and alters the already existing stress state. In order to minimize or eliminate these adverse effects, machine-shop personnel often experiment with a number of process parameters, for example, depth of cut, speed of the cutting tool, and coolant. For single-point turning, they frequently flip the workpiece in order to balance the distortions and stresses evenly on the two sides. This trial and error is frequently combined with statistical process control.

A serious problem associated with machining and residual stresses is often manifested in the form of part distortion. For example, consider the example in Table 1 (Ref 12). The table shows the results of a dimensional check on 30 samples of an aircraft engine part that was made by machining heat treated forgings procured from three different vendors (10 samples each). The location at which the dimensional check was performed is identified on the figure included in the table. It was found that: (1) for all forgings from any one vendor, the drop was almost identical; (2) the drop in forgings from vendor B was within the specifications, but not so in the case of the other two vendors; and (3) the drop in forgings from vendors A and C was on the two opposite sides of that from vendor B. It was recognized that all heat treated forgings contained residual stresses. When these forgings were machined to net shapes, distortions occurred for two reasons: the release of residual stresses from the removed portion of the workpiece and the machining process itself. The former can be easily modeled using the finite element method if the magnitude of residual stresses in the forgings prior to machining is known (Ref 5). However, to this author's knowledge, no serious attempt has so far been made to predict residual stresses in a workpiece due to the machining process itself. If an attempt of this type is to provide reliable results, it must take into account such factors as: depth of cut, speed of the cutting tool, interaction between the tool and the workpiece (heat and force), coolant, and clamping/unclamping of the workpiece. It must also recognize the fact that the location of contact between the tool and the workpiece moves as the machining process progresses. If such technology could be developed, it would become possible to predict and control the overall distortions and residual stresses in a part after machining, thereby reducing scrap.

Welding. The residual stress distribution in welded joints depends on a number of process and design parameters such as the heat input, speed of the welding arc, preheat, thickness of the welded part, groove geometry, and weld schedule. Welding engineers have long used trial and error to obtain a suitable combination of these parameters in order to control the residual stresses.

The role of computer simulation in the prediction of residual stresses in weldments is the subject of a recent review (Ref 14). Major elements of computer simulation of the process are:

- Mathematical representation of the heat input from the welding source
- A transient thermal analysis
- A transient stress/displacement analysis; the flow of molten metal and thermal convection in the weld pool are generally ignored

Following Rosenthal (Ref 41), a semisteady state approach is often used, although some attempts at full three-dimensional analysis have also been made. As mentioned earlier, it is now possible to account for volumetric change and transformation plasticity effects. Because of the short time periods involved, creep is ignored. In the case of a single-pass weld or a weld with few passes (e.g., four or five), it is now possible to predict residual stresses with reasonable accuracy. But, as the number of passes increases (e.g., 20 or 30), it becomes computationally intractable to model each pass. The scheme of lumping several passes into one layer has been employed with less than satisfactory results. In addition to excessive computation time, other major difficulties with the simulation of a multipass weld are: the numerical errors tend to accumulate with each pass, and the changes in metallurgical and mechanical properties of material in previously deposited layers during deposition of a subsequent layer are difficult to quantify and to account for in the finite element analysis. The technique of lumping several layers together aggravates these problems.

Between the mid 1970s and early 1980s, the Electric Power Research Institute (EPRI) in the United States sponsored a program to systematically study the effects of various process and geometric parameters such as the heat input, welding method (gas tungsten arc welding, submerged arc welding, laser, and plasma), speed of the welding arc, diameter and thickness of the pipe, and groove geometry, on residual stresses in pipe welds (Ref 42, 43, 44, 45, 46, 47, 48, 49, 50, and 51). In addition, various thermal processes such as heat-sink welding, backlay welding, and induction heat treatment were investigated to verify if the residual stresses on the inner surface of the pipe could be changed from tensile to compressive to avoid intergranular stress-corrosion cracking. Both experimental and finite element methods were used in the study. The results of this effort are summarized in Ref 52.

A very interesting effort related to in-process control and reduction of residual stresses and distortions in weldments is being pursued (Ref 53, 54). The effort aims at moving beyond mere analysis of residual stresses and distortions to aggressively controlling and reducing them. To accomplish this objective, the effort is subdivided into the development of the following three primary capabilities: prediction, sensing, and control. For prediction purposes, a series of computer programs have been developed, include simple but fast one-dimensional programs that analyze only the most important stress component, that is, the one parallel to the weld line. Sensing capability refers to a set of devices including a laser interferometer to measure minute amounts of distortions, a laser vision system to measure large amounts of distortions, and a mechanical system to measure radi of curvature. Finally, to control the residual stresses, various techniques including changes in heating pattern and application of additional forces have been attempted. References 53 and 54 provide further examples of the application of this methodology in reduction of residual stresses in weldments in high-strength steels and girth-welded pipes.

Coating. Coatings are being used extensively in aerospace, marine, automobile, biomedical, electronics, and other industries. For example, in modern jet aircraft engines, approximately 75% of all components are coated. Some of the reasons for the application of coatings are: thermal barrier, wear resistance, corrosion resistance, oxidation protection, electrical resistance, and repair or dimensional restoration of worn parts. A variety of methods are used for the deposition of coatings on a substrate; the following discussion is limited primarily to the thermal spray process.

The prediction of residual stresses in a coating/substrate system is in its infancy. These stresses result from the difference in the coefficient of thermal expansion of the coating and substrate materials and from plastic deformation of the substrate material. The limited number of numerical studies conducted thus far have been related to small button-type specimens where the coating material was assumed to be fully molten and deposited instantaneously. These efforts have ignored several important factors, for example:

- The presence of partially molten particles in the spray
- A nonuniform deposition of coating material normal to the axis of the plasma jet
- A liquid-to-solid and solid-state transformation
- Imperfect bond between the coating and the substrate
- The relative motion between the spray and the substrate

Also, because a layer of coating consists of several successive passes, the effect of any new pass on its adjacent previously deposited pass in terms of partial remelting, additional material buildup, solute diffusion, and redistribution of residual stresses could be important and should be accounted for. If more than one layer is involved, for example, in functionally graded coatings, modeling the effect of a whole new layer of material on the previously deposited layer would be computationally prohibitive. Also, due to the morphology of the coating material on deposition, its thermal and mechanical properties are extremely difficult to measure and, thus, are generally unavailable for simulation purposes. Due to such reasons, end-users of coated products still rely on the methods of trial and error and statistical process control for the selection of an optimal combination of process parameters in order to control the residual stresses in coated parts (Ref 55).

Control of Residual Stresses

U. Chandra, Concurrent Technologies Corporation

Stress-Relief Methods

The basic premise of a stress-relief method is to produce rearrangement of atoms or molecules from their momentary equilibrium position (higher residual stress state) to more stable positions associated with lower potential energy or stress state. These methods can be classified into three broad categories: thermal, mechanical, and chemical (Ref 4, p 134). The following concern the methods in the first two categories.

Thermal stress-relief methods include annealing, aging, reheat treatment (e.g., postweld heat treatment), and others. In general, a stress-relief operation involves heating the part to a certain temperature, holding at the elevated temperature for a specified length of time, followed by cooling to room temperature. Primary reduction in residual stresses takes place during the holding period due to creep and relaxation. Thus, computer simulation of a thermal stress-relief method generally entails a thermal-elastic-plastic-creep analysis of the part. A simple, one-dimensional computer analysis of residual stresses in thin plates along with experimental verification is discussed by Agapakis and Masubuchi (Ref 56). More sophisticated thermal-elastic-plastic-creep simulations of the annealing of single pass and multipass girth-butt welds in pipes are presented in Ref 57 and 58.

A number of subcategories of mechanical stress-relief methods are listed in Ref 4. Of these, the methods in the static-stressing subcategory such as stretching, upsetting, bending and straightening, and autofrettage are common, and these should not pose much difficulty in simulation by the finite element method. Similarly, in the mechanical surface treatment subcategory, it should be possible to model the surface-rolling method. However, within the same subcategory, shot peening (a frequently used stress-relief method) is likely to be difficult to simulate; and to this author's knowledge, no realistic attempt has yet been made to do so. The obvious reason is that, whereas it should be possible to model a single impact, modeling multiple impacts will be difficult, just as it is for modeling multipass welding.

In recent years, the method of vibratory stress relief (especially in the subresonant region) has received considerable attention (Ref 59, 60). The basic premise of this method is that the presence of residual stresses in a part changes (increases) its natural resonant frequency. When the part is subjected to vibrations below its new frequency, the metal absorbs energy. During this process, the stresses redistribute gradually and the resonant frequency shifts back to the point corresponding to a residual stress-free (or almost free) state. The process does not change the metallurgical or mechanical properties of the material. The technique has been found successful in relieving residual stresses induced by thermal processes such as welding and casting, but not those induced by cold working. It has also been applied to reduce residual stresses in parts prior to machining in order to minimize distortions. It has been found particularly beneficial in low- and medium-carbon steels, stainless steels, and aluminum alloys, but not in copper alloys. In view of the fact that the technique is much simpler, quicker, and more inexpensive than the thermal-relief methods, it merits further study.

Design for Surface Finishing

Eric W. Brooman, Concurrent Technologies Corporation

Introduction

AN AXIOM among surface-finishing industry professionals is that the quality of a finish is only as good as the quality of the substrate and its pretreatment. That is, to obtain a finish of high quality, meeting all performance specifications and

customer expectations, great care has to be taken in identifying and using the appropriate pretreatment. The latter could be grinding, heating, buffing, cleaning, or a number of other processes to prepare the surface properly. Although not articulated in quite the same way, the surface-finishing industry also recognizes that the design of the part (component or assembly) can have a significant influence on the ability to use satisfactory pretreatments and obtain quality finishes. The overall part design, and the design of surface features and their size, can have an impact not only on the choice of pretreatments and finishes, but also on the efficacy of these processes and the results obtained. This article provides some guidelines about general design principles for different types of surface-finishing processes, which include cleaning, organic coatings, and inorganic coatings applied by a variety of techniques.

Many of the guidelines discussed here apply equally as well to other articles in this section and vice versa. Therefore, although what is presented here is a fairly comprehensive summary of the topic of design for surface finishing, useful information can be found in other articles such as "Design for Machining" and "Design for Heat Treatment." As is stressed elsewhere and discussed in this article, design must be considered an integral part of the overall manufacturing process and cannot be considered in isolation.

Definitions and more detailed descriptions of the processes discussed in this article can be found in *Surface Engineering,* Volume 5 of *ASM Handbook.*

Eric W. Brooman, Concurrent Technologies Corporation

Design as an Integral Part of Manufacturing

In recent years, manufacturing processes have been evaluated in terms of life-cycle costs and their impact on the environment, and even ecology in general. Several scenarios have been proposed for the life cycle of materials, which of necessity incorporates manufacturing processes. In the article "Introduction to Manufacturing and Design" in this Volume, an example of one such scheme is given where a material flows through the extraction, refining (preparation), shapemaking and structural treatments (manufacturing), and surfacing (surface-finishing) stages before being assembled and placed in use. Manufacturing also can be viewed as part of an "integrated product- and process-development" process, also described in that article. This approach places emphasis on "product design" and "process design" in a concurrent-engineering environment and forces product developers to consider both simultaneously, rather than sequentially and separately (Ref 1). If these concepts are extrapolated, with a focus on design in relation to surface finishing, the iterative process shown in Fig. 1 results. The scheme presented in this figure is entirely consistent with another modern manufacturing concept, namely that of continuous improvement.

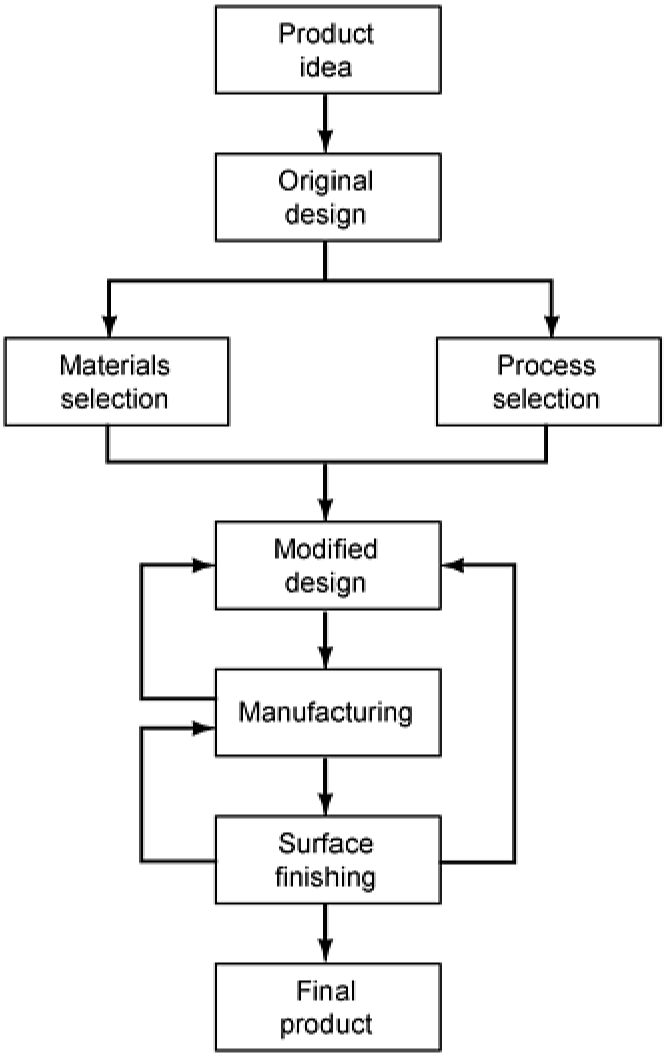

Fig. 1 Flow diagram for incorporating design principles into surface-finishing operations

Having stressed the importance of considering design precepts as an integral part of the manufacturing process and product improvement, the following guidelines should be considered as just that--guidelines. Each application should be treated on an individual basis, and surface-finishing processes should be flexible enough to permit design improvements, and vice versa. In addition, it should be obvious from Fig. 1 that the earlier in the product-development cycle manufacturing-related design considerations are addressed, the more efficient will be the manufacturing process and the better the quality of the surface finish will be. Communication with and input from the manufacturing and surface-finishing staff are very important in establishing a satisfactory product design.

Design of the part or component and pretreatment selections are important, but in keeping with the concept of design being an integral part of manufacturing and surface finishing, process equipment design restrictions and fixturing design also are very important. Both can influence the quality of the resulting finish. Figure 2 shows their interrelated roles schematically. In this overview, emphasis is placed on issues relating to part design and process equipment. Fixturing must be designed and tailored for each individual application and is beyond the scope of this article.

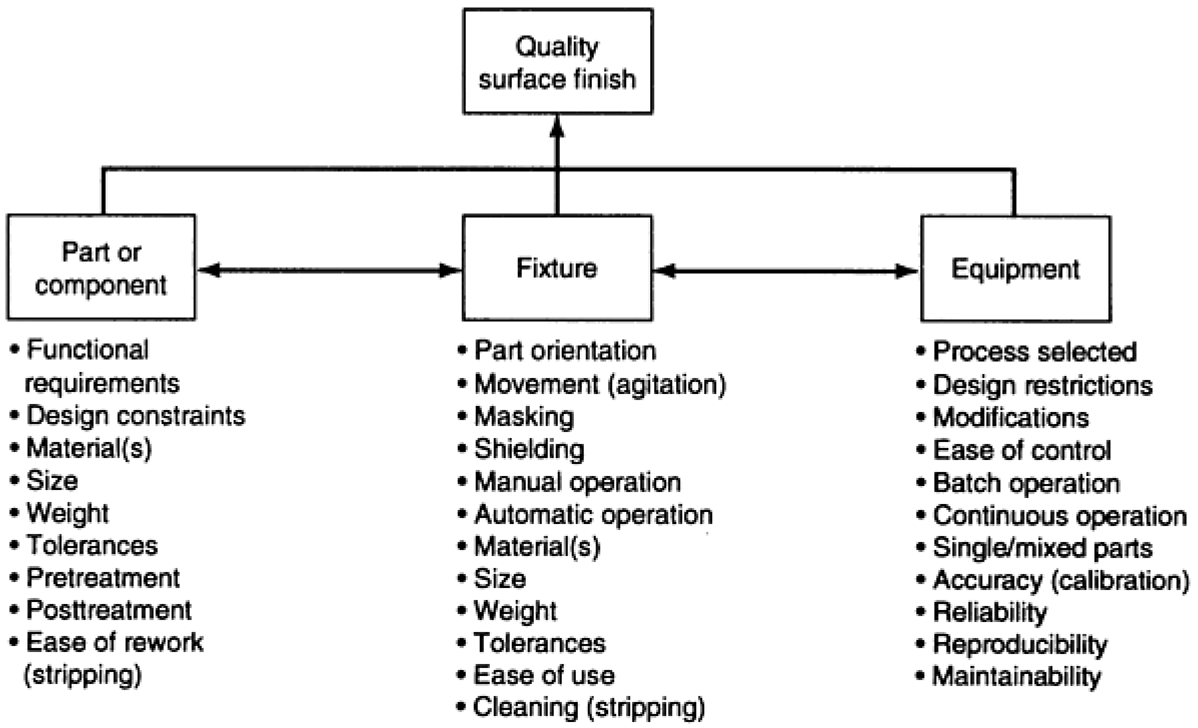

Fig. 2 Interrelation between part design, equipment limitations, and fixturing

General Design Principles Related to Surface Finishing

There are a number of general design principles that apply to a variety of finishing processes, while others are specific to individual finishing techniques. These general principles are discussed in this section, and the following three sections discuss design aspects relating to: (1) surface-preparation techniques, including cleaning; (2) organic finishing techniques; and (3) inorganic finishing techniques. References 2 and 3 provide some background material on the various finishing techniques discussed, while Tables 1, 2, and 3 summarize the important design limitations for these three categories. The subject of materials selection is covered elsewhere in this Volume. The choice of materials can limit the choices for surface finishing. Where appropriate, significant limitations are described.

Table 1 Summary of design limitations for selected surface-preparation processes

Process	Design limitations
Blasting/deburring	Avoid recesses, holes, channels, and similar features (such as closely spaced ribs) that could trap blasting media
	Avoid thin cross sections (such as fins, louvers, walls) that could be distorted by the blasting media
	Avoid intricate designs and surface features
Broaching/honing	Typically used for inside diameters of tubes and other cylindrical parts, or for grooves, large holes, and other cavities

	Surfaces must be accessible to tools and withstand the local pressure and heat buildup
	Avoid very thin cross sections/wall thickness
Brushing/burnishing	Surfaces must be accessible to tools and withstand the local pressure and heat buildup
	Avoid very thin cross sections/wall thickness that could deflect
	Avoid sharp corners and edges
	Avoid intricate designs and surface features
Chemical milling	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air or evolved gases and prevent chemical action from occurring or cause uneven attack
	Mask areas not to be attacked
Conversion coating	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent surface chemical reactions from occurring or cause staining
	Mask areas not to be attacked
Electrocleaning	Allow for electrical contact to be made on nonsignificant surfaces
	Avoid features that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air or evolved gases and would prevent cleaning from occurring or cause staining
Electropolishing	Allow for electrical contact to be made on nonsignificant surfaces
	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air or evolved gases and prevent polishing action from occurring or cause staining
	Mask areas not to be attacked
Etching	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent etching action from occurring
	Avoid sharp corners and edges
	Avoid shallow intricate designs and surface features
	Mask areas not to be attacked
Grinding	Surfaces must be accessible to tools and withstand the local pressure and heat buildup
	Avoid very thin cross sections/wall thickness
	Avoid sharp corners, edges, and protuberances
	Avoid intricate designs and surface features
Lapping/buffing	Surfaces must be accessible to tools (preferably flat or simple, curved contours
	Avoid very thin cross sections/wall thickness that cannot withstand the local pressure and heat buildup
	Avoid sharp corners and edges
	Avoid intricate designs and surface features that would trap the lapping/buffing compounds
Pickling	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent pickling action
	Avoid flat surfaces on small parts that could stick together, exclude the acid, and prevent the pickling action
Polishing	Surfaces must be accessible to tools and withstand the local pressure and heat buildup
	Avoid very thin cross sections/wall thickness
	Avoid sharp corners, edges, and protuberances
	Avoid intricate designs and surface features that could trap the polishing compound
Solvent cleaning, immersion	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent cleaning from occurring
	Avoid flat or curved surfaces on small parts that could stick together during immersion and prevent cleaning of those surfaces
Solvent cleaning, ultrasonic	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent cleaning from occurring
	Avoid thin cross sections that could be damaged by the energy released during cavitation

Stripping, chemical	Avoid features (e.g., small recesses, blind holes, cavities) that would trap smut and process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent coating removal from occurring
	Mask areas not to be attacked
Stripping, mechanical	Avoid recesses, holes, channels, and similar features that could trap blasting media
	Avoid thin cross sections or intricate designs that could be damaged by the stripping media
	Mask areas not to be attacked
Stripping, thermal	Avoid thin cross sections or intricate designs that could be distorted by the thermal cycling
	Try to provide uniform cross-sectional mass throughout the part to help provide a uniform temperature distribution during heating

Table 2 Summary of design limitations for selected organic finishing processes

Process	Design limitations
Electrocoating	Allow for electrical contact to be made on nonsignificant surfaces
	Avoid features that could trap air and prevent wetting by process solutions
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid thin cross sections or intricate designs that could become distorted during drying/curing cycle
Electropolymerization	Allow for electrical contact to be made on nonsignificant surfaces
	Avoid features that could trap air and prevent wetting by process solutions
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid thin cross sections or intricate designs that could become distorted during drying/curing cycle
Painting, brushing or dipping	Surfaces must be accessible to application tools (preferably flat or simple, curved contours)
	Avoid features that would trap excess paint
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent coating from occurring
	Avoid thin cross sections or intricate designs that could become distorted during drying/curing cycle
Painting, solvent spraying	Surfaces must be accessible to application tools (preferably flat or simple, curved contours)
	Allow for fixturing/racking on nonsignificant surfaces
	Avoid features that would trap excess paint
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent coating from occurring
	Avoid thin cross sections or intricate designs that could become distorted during drying/curing cycle
Powder coating	Allow for fixturing/racking on nonsignificant surfaces
	Allow for electrical contact to be made on nonsignificant surfaces
	Avoid deep recesses and blind holes that cause the "Faraday cage" effect
	Avoid thin cross sections or intricate designs that could become distorted during drying/curing cycle
Sol-gel coating	Allow for fixturing/racking on nonsignificant surfaces
	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals
	Avoid thin cross sections or intricate designs that could be distorted by the thermal cycling
	Try to provide uniform cross-sectional mass throughout the part to help provide a uniform temperature distribution during heating cycle
Solution coating	Allow for fixturing/racking on nonsignificant surfaces
	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent coating from occurring
	Avoid thin cross sections or intricate designs that could become distorted during drying/curing cycle

Table 3 Summary of design limitations for selected inorganic finishing processes

Process	Design limitations
Anodizing	Allow for electrical contact to be made on nonsignificant surfaces
	Avoid, if possible, sharp edges and corners, ridges, blind holes, etc., that would prevent uniform density distribution
	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent electrochemical reactions from occurring
	Avoid features that could trap evolved gases and cause staining
	Mask areas not to be anodized
Cementation/diffusion	Surfaces must be thoroughly deburred and cleaned before cladding, so design principles for these processes also apply

	Avoid thin cross sections or intricate designs that could become distorted during thermal cycling
	Mask areas not to be coated
Cladding	Only for relatively simple shapes, especially with flat surfaces
	Surfaces must be thoroughly cleaned before cladding, so design principles for cleaning also apply
Electroless plating	Allow for fixturing/racking on nonsignificant surfaces
	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent chemical reactions from occurring or cause staining
	Mask areas not to be coated
Electrophoretic plating	Allow for electrical contact to be made on nonsignificant surfaces
	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent surface chemical reactions from occurring or cause staining
	Mask areas not to be coated
Electroplating (plating, electrodeposition)	Allow for electrical contact to be made on nonsignificant surfaces
	Avoid, if possible, sharp edges and corners, ridges, blind holes, etc., that would prevent uniform current density distribution; or use current robbers and/or shields
	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent deposition from occurring
	Avoid features that could trap evolved gases and cause staining
	Avoid thin cross sections (such as fins, louvers, walls) that could be distorted by internal stress in the coating
	Mask areas not to be coated
Hot dipping, galvanizing	Allow for fixturing/racking on nonsignificant surfaces for discrete, small parts
	Best for relatively simple shapes (e.g., tubing) and flat surfaces
	Allow for excess coating material to drain quickly
	Allow for doctor blades or air knives to be used to obtain uniform coating thickness
	Avoid thin cross sections that could become distorted during thermal cycling
Inorganic painting, slurry coating	Surfaces must be accessible (preferably flat or simple, curved contours)
	Allow for fixturing/racking on nonsignificant surfaces
	Avoid features that would trap excess paint
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Avoid features that could trap air and prevent coating from occurring
	Avoid thin cross sections or intricate designs that could become distorted during drying/fusing cycle
	Mask areas not to be coated
Ion implantation	Allow for electrical contact to be made on nonsignificant surfaces or use a conductive screen
	Avoid features that would shield the surface from the beam (line-of-sight limited) unless multiple beams are used or part is rotated/translated in beam
	Avoid high aspect ratio holes and recesses, grooves, etc., that would not allow the beam to reach the bottom surfaces
	Mask areas not to be coated
Ion plating	Allow for electrical contact to be made on nonsignificant surfaces or use a conductive screen
	Avoid features that would shield the surface from the beam (line-of-sight limited) unless multiple beams are used or part is rotated/translated in beam
	Avoid high aspect ratio holes and recesses, grooves, etc., that would not allow the beam to reach the bottom surfaces
	Mask areas not to be coated
Laser glazing	Allow for fixturing/racking on nonsignificant surfaces
	Avoid features that would shield the surface from the laser beam (line-of-sight limited) unless multiple beams are used or part is rotated/translated in beam
	Avoid high aspect ratio holes and recesses, grooves, etc., that would not allow the beam to reach the bottom surfaces
	Avoid thin cross sections or intricate designs that could be damaged by local heating during glazing
	Mask areas not to be treated
Mechanical (peen) plating	Allow for fixturing/racking on nonsignificant surfaces on large parts

	Avoid features that could trap air and prevent activation by the process chemicals from occurring
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover of activating solutions
	Avoid recesses, holes, channels, and similar features that could trap peening media
	Avoid thin cross sections (such as fins, louvers, walls) that could be distorted by the peening action
	Avoid sharp edges and corners that could be damaged by the peening media
	Avoid intricate designs and small surface features that cannot be reached by the peening media
	Provide good natural drainage or use drainage holes on nonsignificant surfaces to minimize carryover
	Mask areas not to be coated
Passivation	Allow for fixturing/racking on nonsignificant surfaces
	Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing
	Avoid features that could trap air and prevent surface chemical reactions from occurring or cause staining
	Mask areas not to be attacked
Thermal spraying	Allow for fixturing/racking on nonsignificant surfaces
	Design should allow for surface roughening to promote adhesion, so blasting design precepts also apply
	Avoid features that would shield the surface from the spray (line-of-sight limited) unless multiple sprays are used or part is rotated/translated in spray plume
	Avoid high aspect ratio holes and recesses, grooves, etc., that would not allow the spray to reach the bottom surfaces
	Avoid thin cross sections (such as fins, louvers, walls) that could be distorted by the local heating and kinetic energy
	Mask areas not to be coated
Vapor deposition (CVD, PVD, RVD)	Allow for fixturing/racking on nonsignificant surfaces
	Avoid thin cross sections (such as fins, louvers, walls) that could be distorted by heating, if needed prior to coating deposition
	Vacuum processes are line-of-sight limited, so similar design precepts to those for ion plating will apply
	Mask areas not to be coated

(a) CVD, chemical vapor deposition; PVD, physical vapor deposition; RVD, reactive vapor deposition

Fabrication Processes. Some methods of fabrication such as the forging, extrusion, molding, and casting of metals and ceramics can lead to surface defects that must be removed by subsequent surface-finishing techniques, such as grinding, lapping, and polishing or electropolishing, or hidden by techniques such as applying a leveling copper deposit before a decorative plated finish. Defects include laps, tears, cracks, pores, shrinkage cavities, gating and venting residues, ejection marks, and parting lines. Careful design of the casting or molding operation--including the dies, gates, vents, and overflows--will minimize finishing problems by ensuring such defects are avoided, occur on nonsignificant surfaces, or are hidden by specially incorporated design features, such as steps or ridges at parting lines.

When polymeric materials are being cast, molded, extruded, or formed, it is especially important that the design and tooling lend themselves to producing an acceptable surface finish because any finishing operation that removes surface layers could expose porosity and other defects and remove aesthetic qualities such as smoothness and luster. Also, the selection of finishing tools and conditions is much more critical because of the physical properties (e.g., softness, plasticity) of the polymeric materials and the potential for damage (e.g., heat distortion) caused by heat generated during the finishing operation. This topic is discussed more fully in Ref 4. As with metals and ceramics, some undesirable attributes of the fabrication process, such as parting lines, can be hidden by added design features.

Whatever the type of material being cast or molded, dimensional and warpage allowances must be made in the design of the tooling (i.e., dies) to accommodate shrinkage and distortion during solidification and cooling. Otherwise, parts may be undersized or require excessive machining to obtain the specified dimensional tolerances.

Control of fastening or joining processes also can influence surface finishing. For example, two flat surfaces riveted together produce cavities that can entrap processing solutions, impair coating, and lead to corrosion (Ref 5). Spot or tack welding is no better in this regard. However, a continuous weld--with a smooth bead and no weld spatter--will prevent this problem and make surface finishing easier. Also, the elimination of sharp edges and corners will prolong the life of grinding, polishing, and buffing belts and wheels.

Size and Weight. The design, dimensions, and weight of a part to be surface finished have a direct influence on fixturing and the size and type of equipment that is used. As Ref 6 points out, size has little to do with production rate. Large parts do not necessarily mean low production rates, but they will dictate the size of the cleaning tanks, spray booths, plating tanks, vacuum chambers, and the like. Nevertheless, the end-use application often dictates the size of a part or component and materials selection will dictate its weight. Consequently, as a variable, only design is left to influence ease of finishing, efficacy of finishing, and finishing cost. Whatever can be done in terms of optimizing a design to facilitate surface finishing will have a positive impact. In this context, design optimization includes facilitating the handling of parts between the various surface-finishing steps, as well as during the processes themselves. These operations will be most efficient when the parts are designed to prevent "nesting" or flat surfaces from sticking together (because of surface tension effects) and preventing those surfaces from being treated or coated. Similarly, small parts may be light in weight and unstable in sprays during pretreatment or painting. The design of these parts should be such that clips or magnets can be used to secure and stabilize them during processing.

Aesthetics and Function. Another general consideration is that not all surfaces may require the same high standard of surface finish. While surfaces exposed to view must be aesthetically pleasing, and surfaces subjected to more aggressive conditions of exposure or use require durable coatings, hidden (internal) surfaces or less-exposed surfaces may not need such a high-quality finish. Specifications for surface finishes for a part depend not only on the design and end-use application, but also must take into account that the requirements may differ for different areas or surfaces on that part. A design should take this into consideration, as well as the fact that different types of equipment or equipment operation settings may be necessary for those areas and surfaces.

Functional requirements of a part also influence the selection of surface preparation processes. For example, grinding processes can introduce stresses that could have a negative impact on fatigue properties. Choosing an alternative process, such as chemical milling, or mitigating the stresses by shot peening can alleviate the problem.

Design Features. Shape and features such as recesses, holes, threads, keyways, slots, fins, and louvers can present problems to the finisher, and the severity of the problem can depend on the finishing technique. For example, when holes are included in thin sections that require a finishing operation such as grinding, if too much pressure is applied edges and corners might be chipped. If only a light pressure is used to avoid this possibility, then the desired finish might not be obtained. Another example is when paint is applied by conventional solvent spraying or when a part is electroplated, bowl-shaped recesses, blind holes, and similar features can trap the paint or plating solution, leading to areas that sag or do not cure properly (in the case of paint), or carry over trapped chemicals to subsequent processing steps (in electroplating). The latter can cause problems such as rinse-water contamination and increased waste-treatment costs. Also, solutions that are trapped can lead to blistering or delamination of the plated coating, especially if there is a posttreatment step that requires the part to be heated (such as for electroless nickel, cadmium, and hard chromium deposition).

For parts that will be sprayed, especially with paint, another problem with deep recesses, closely spaced, large fins or partitions, and the like is the entrapment of air. The back pressure of entrapped air causes incomplete coverage at the bottom of the recesses. One way to avoid this problem, if a change of design is not possible, is to use an "airless" spraying technique (Ref 6). During electrostatic powder coating there is the problem associated with "Faraday cage" effect, in which the charged components of the powder-coating system are attracted by the high fields at the edges and corners of parts, causing excessive coverage there and incomplete coverage in other areas (Ref 7), as shown in Fig. 3. Rounding corners and edges, tapering the sides and decreasing the depth of recesses, minimizing the use of louvers or fins, or changing their dimensions are ways to avoid the Faraday cage effect. In electroplating, a similar phenomenon exists whereby the depositing metal or alloy ions are attracted to the high-current-density areas at edges and corners, and thicker coatings are obtained in those locations. Rounding such edges, changing dimensions to allow for the excessive buildup, or using shields and current "robbers" or "thieves" will help the finisher to obtain the desired coating thickness distribution. Reference 8 provides some examples of the use of such devices.

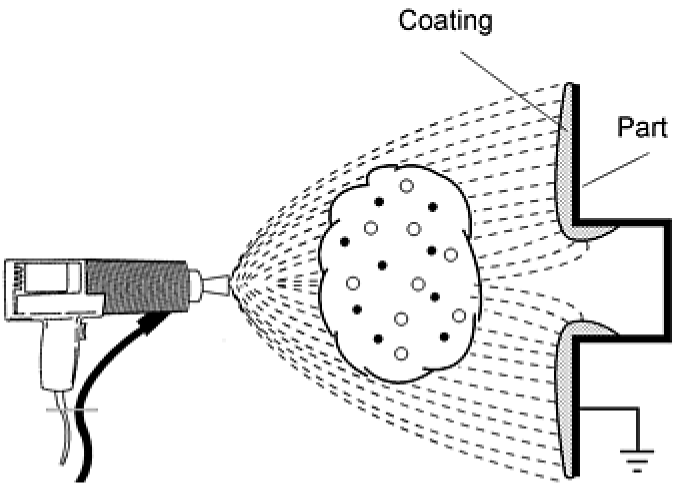

Fig. 3 Faraday cage effect in powder coating. Adapted from Ref 7

In conventional paint spraying and many vacuum-deposition techniques, such as ion plating, ion implantation, physical vapor deposition, and sputtering, attention has to be paid to the limitations imposed by the "line-of-sight" deposition process. Certain features, such as ridges, flanges, and fins, can shadow or mask areas behind them leading to incomplete or nonuniform coverage, as shown in Fig. 4 and 5. Similarly, if the aspect ratio of holes and recesses is too high (i.e., the depth is much greater than the diameter of the opening), it is not possible with line-of-sight limited techniques to penetrate to the bottom surfaces and coat them (Fig. 5). Decreasing the aspect ratio, providing rounded edges, and tapering the sides of ridges and fins or holes will help to facilitate finishing, as will lowering the height of features such as fins. Of course, rotating or translating a part in the spray plume also will help to obtain complete and more uniform coverage, but this approach usually requires longer times and more sophisticated finishing equipment and fixturing; hence, it often leads to higher costs. The same can be said for using multiple line-of-sight sources to obtain better coverage.

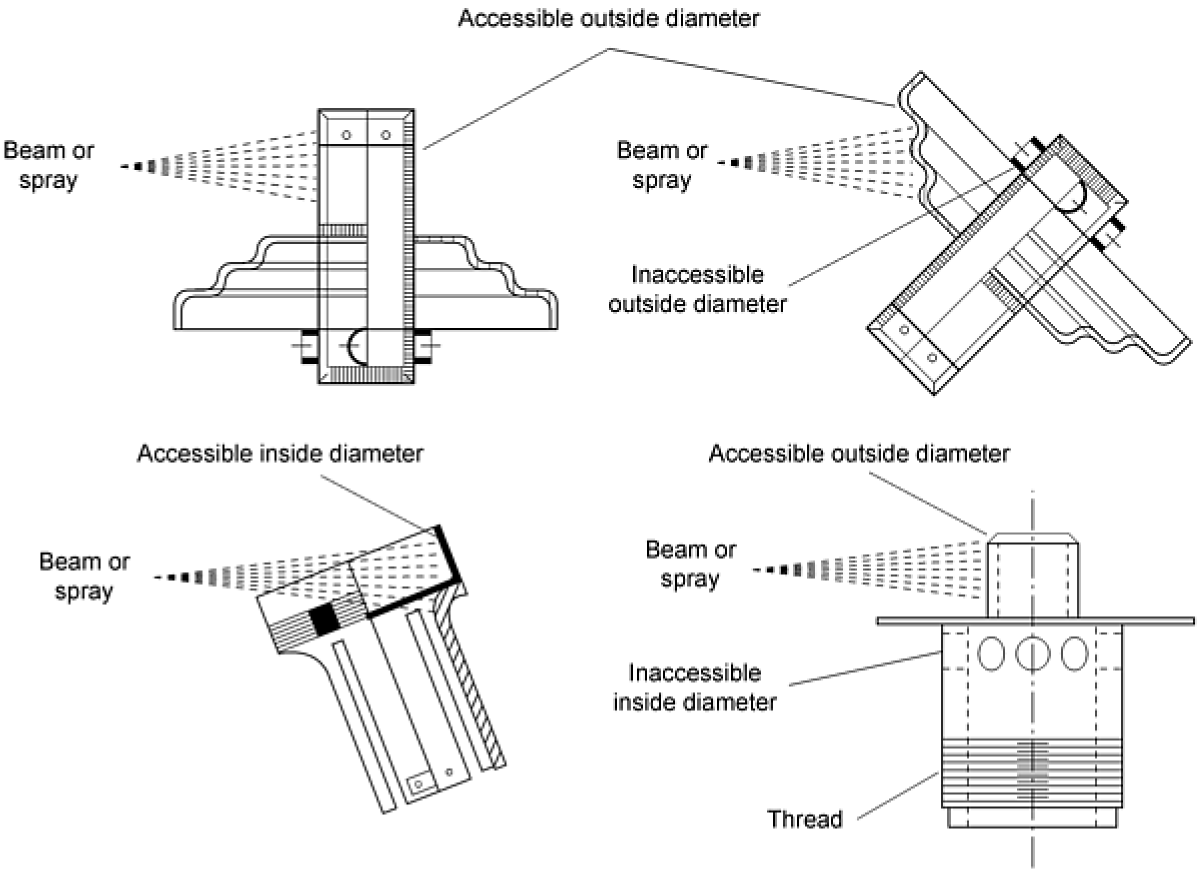

Fig. 4 Some examples of line-of-sight limitations in spraying or ion-beam coating processes

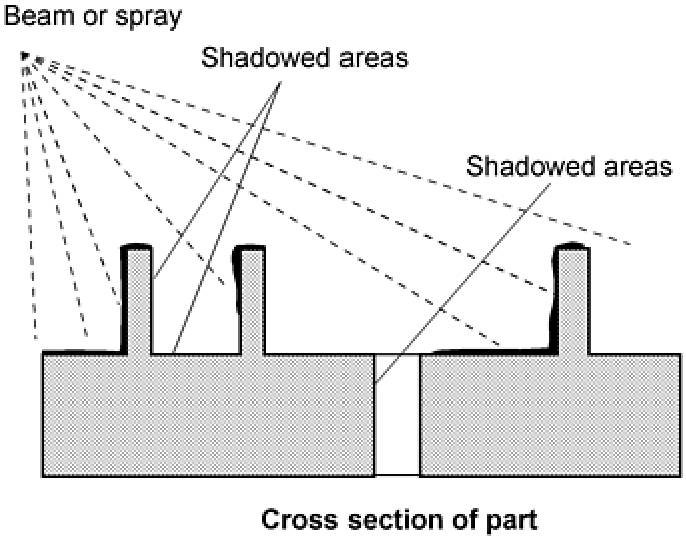

Fig. 5 Design features that cause shadowing or poor coverage because of line-of-sight limitations

Finally, as a general rule of thumb, parts of the same size, weight, design, and material should always be finished at the same time so that the finishing process(es) can be optimized for those parts. Batches of mixed parts should be avoided unless they share some common features, such as shape and substrate material.

Design for Surface Finishing

Eric W. Brooman, Concurrent Technologies Corporation

Surface-Preparation Processes

To facilitate surface preparation--including cleaning--prior to subsequent coating operations, design precepts should have been considered during the product-design and manufacturing stages, as indicated in Fig. 1. Abrupt changes in surface contours should be avoided, and features such as fine grooves, recesses, surface patterning, blind holes, and reentrant areas should be avoided because they will be inaccessible to polishing media or would trap polishing media, making subsequent cleaning more difficult. Such features also would entrap cleaning chemicals, making rinsing more difficult, or could possibly entrap air, preventing cleaning of these areas.

Sharp corners and edges or protrusions can cause excessive wear of polishing wheels and belts and lead to uneven polishing because the high areas are polished at the expense of the surrounding lower areas. As mentioned earlier, rounding edges and corners is a good design precept, while minimizing the height of protuberances is beneficial, as is decreasing the aspect ratio of holes, grooves, and recesses.

Large expanses of flat surfaces may be a problem if these are significant surfaces, especially if these surfaces must be polished to a reflective, mirrorlike finish. Imperfections are exaggerated. Minimizing the area of such surfaces and providing a slightly rounded contour will help to attain the desired finish and help with visual appearance.

Simpler designs lend themselves to automatic finishing processes, while more complex designs may require manual surface-preparation techniques. If parts are to be mass finished (e.g., by tumbling or vibratory finishing) significant flat areas should be avoided. Otherwise, parts may stick together, and these occluded surfaces will not be finished. Designs that prevent access by the deburring or polishing media (such as small recesses and holes) or that entrap the media (such as narrowly spaced ribs) should be avoided as mentioned above.

When it is impractical or impossible to use mechanical polishing, chemical etching, chemical milling, or electropolishing can be used. The design principles for the latter are similar to those for electroplating, which is discussed later. In electropolishing, the workpiece is the anode, which is the opposite of electroplating. Current density distribution is extremely important, as is the original surface of the part being electropolished. In high-current-density areas on susceptible materials, the surface layers may be removed and etching of the substrate can occur. Polishing occurs on a microscopic scale, so macro features such as large grooves or scratch marks will not be removed but will receive a luster and become more noticeable. Similarly, parting lines can be smoothed, but not removed; therefore, parting lines must be minimized by good die design and careful molding operations.

Solvent cleaning is a fairly forgiving surface-finishing process, but part design can influence its efficacy, as already alluded to. If agitation or other cleaning aids are used, such as ultrasonic energy, care must be taken to prevent soft materials or thin and fragile features or cross sections from being damaged. The energy released during cavitation, for

example, in ultrasonic cleaning is very large. If techniques such as plastic media blasting are used, the blasting parameters should be tailored to the part material and design, and the part should be designed to allow easy access by the media and easy removal of the media once the desired finish (cleanliness) is obtained.

If a power spray washing technique is used, the part design should allow for proper drainage to conserve chemicals and minimize carryover to the next process step. Providing drainage holes may be necessary. These should be either a natural feature of the design or located on nonsignificant surfaces. As the design of a part becomes more complex, rinsing requirements become more stringent, and several rinsing stages may be necessary. If an air knife is used afterward to remove excess water, the part must be capable of withstanding the pressure or must be fixtured such that the air pressure does not distort any delicate design features while holding the part steady.

Table 1 provides a summary of the design limitations of some surface-preparation and cleaning processes and indicates which design features to avoid.

Eric W. Brooman, Concurrent Technologies Corporation

Organic Finishing Processes

Organic finishes are applied by a variety of techniques, such as dipping, brushing, spraying, airless spraying, or electrostatic spraying. In addition, some primers are deposited using electrophoretic techniques, while electropolymerization is being looked at for certain types of organic coatings. Table 2 summarizes these techniques and the design limitations associated with each.

Most of the techniques are line-of-sight limited, and the guidelines provided in the previous section, "Surface-Preparation Processes," will apply. Allowance for drainage is important for processes that involve dripping or spraying. Avoiding sags and runs on large, flat, vertical surfaces can be accomplished by applying good coating practices and by minimizing such surfaces in the design of the part.

A few organic coating techniques use electric or electrostatic fields. Designing the fixtures and electrical grounding, such that points of contact are on nonsignificant surfaces, will improve the appearance of the coated part and give the impression of a better quality product. With spraying techniques, proper fixturing and racking of parts can improve the use of coating material because less empty space exists during a run. However, the parts should not be racked so closely together that they shield some surfaces and prevent some areas from being coated.

Avoiding thin cross sections and good fixturing will help prevent distortion during the curing and baking steps used after paint or powder is applied.

Optimizing a design for surface finishing, such as painting, becomes very important as coating thickness is reduced to 30 μm or less. Access to all surfaces must be possible and any features that would prevent this should be avoided (see the section "Design Features" in this article). This is because the dimensions of the solid components in the coating formulation (e.g., powder particle) are similar to the dimensions of the desired dry film thickness (Ref 9). For example, during the first part of curing, when the particles liquefy, the surface tension of the film formed will tend to pull it away from sharp corners or edges, resulting in poor coverage. If a design modification is not possible, the powder formulation should be changed to include higher-viscosity resins, and no, or only small amounts, of surfactants (Ref 9). Thin-film coatings are best applied to parts with simple geometries, with flat or curved surfaces, and few sharp edges.

Earlier, the problem with the Faraday cage effect was mentioned. This phenomenon is further complicated by back-ionization with traditional corona-charging systems (Ref 7). Not only does the design of a recess, hole, or channel control the distribution of coating thickness, but the buildup of back-ionization at the areas of high field intensity lowers the effective charge of the powder particles, further reducing their ability to reach the bottom surfaces. Some possible design modifications were mentioned earlier but, if these are not possible, changing to a turbocharging system will help. Back-ionization is greatly reduced, and the absence of free ions between the gun and the part promotes better coverage of all surfaces (Ref 7).

Design for Surface Finishing

Eric W. Brooman, Concurrent Technologies Corporation

Inorganic Finishing Processes

Inorganic finishes--including metal- and ceramic-based coatings--are applied by a variety of techniques, such as electroplating, electroless plating, thermal spraying, hot dipping, ion plating, and various vapor-deposition techniques. Other techniques, such as ion implantation and laser glazing, modify surface properties. Table 3 summarizes design limitations for these and other types of inorganic coating processes.

Electroplating is widely used in industry to apply inorganic coatings, especially metals and alloys. Like some organic finishing processes, satisfactory coatings are only obtained when a uniform current density can be established on all surfaces to be finished. Phenomena like the Faraday cage effect occur when design features prevent the establishment of a uniform current density distribution. As mentioned earlier, techniques relating to fixturing and racking can alleviate some of the problems. General design approaches are discussed in Ref 8 and 10 and summarized in Table 4.

Table 4 Design features that influence electroplating

Design feature	Influence on platability	Better design
	**Convex surface.** Ideal shape. Easy to plate to uniform thickness, especially where edges are rounded.	
	Flat surface. Not as desirable as crowned surface. Use 0.015 mm/mm (0.015 in./in.) crown to hide undulations caused by uneven buffing.	
	Sharply angled edge. Undesirable. Reduced thickness of plate at center areas. Requires increased plating time for depositing minimum thickness of durable plate. All edges should be rounded. Edges that contact painted surfaces should have a 0.8 mm ($\frac{1}{32}$ in.) min radius.	
	**Flange.** Large flange with sharp inside angles should be avoided to minimize plating costs. Use generous radius on inside angles and taper abutment.		**Slots.** Narrow, closely spaced slots and holes cannot be plated properly with some metals (e.g., nickel and chromium) unless corners are rounded.	
	**Blind hole.** Must usually be exempted from minimum thickness requirements.		Sharply angled indentation. Increases plating time and cost for attaining a specified minimum thickness and reduces the durability of the plated part.	
	Flat-bottom groove. Inside and outside angles should be rounded generously to minimize plating costs.	
	**V-shaped groove.** Deep grooves cannot be plated satisfactorily; should be avoided. Shallow, rounded grooves are better.	
	**Fins.** Increase plating time and costs for attaining a specified minimum thickness and reduce the durability of the plated part.	
	Ribs. Narrow ribs with sharp angles usually reduce platability; wide ribs with rounded edges impose no problem. Taper each rib from its center to both sides and round off edges. Increase spacing, if possible.		Deep scoop. Increases time and cost for plating specified minimum thickness.		Spearlike jut. Buildup on jut robs corners of electroplate. Crown base and round all corners.		**Ring.** Platability depends on dimensions. Round corners; crown from center line, sloping toward both sides.	

Note: Distribution of electroplate on design shapes is intentionally exaggerated by solid black outline. Cross-hatched areas indicate part before plating.

With the plating of fasteners, some special considerations apply, particularly in respect to threads (Ref 10). As might be expected, electroplated metals build up faster on apexes of the threads, and coverage can be minimal at the bottom of the grooves. ANSI Specification B 1.1 states that, compared to flat surfaces, plating thickness builds up six times faster on the major diameter than the minor diameter and that this results in a fourfold buildup on the pitch diameter, as illustrated in Fig. 6. This is known as the "Rule of Four and Six."

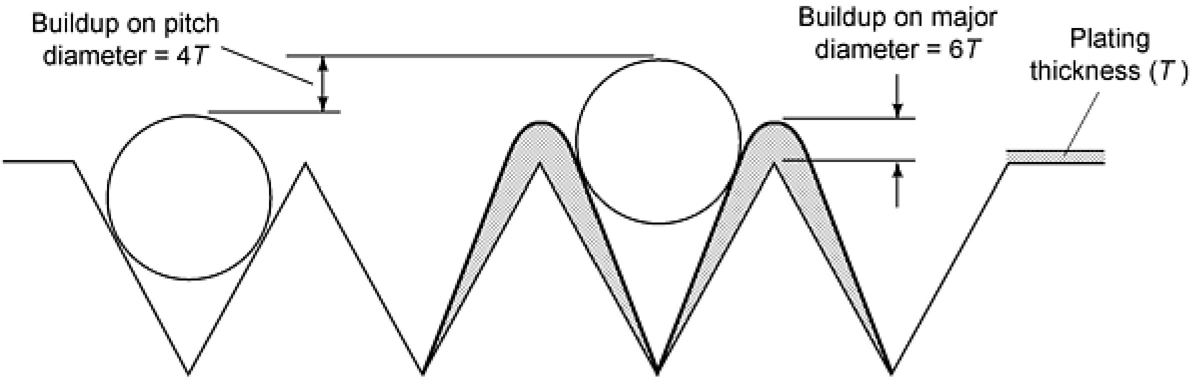

Fig. 6 Rule of Four and Six as applied to coating external threads. Source: Ref 10

Similarly, plating inside holes can be difficult. The general rule of thumb is that if the hole diameter is *x*, the plating will occur to a depth of 2*x*. However, for blind holes, plating will only occur to a depth of *x*. Agitation, solution flow, maximizing the throwing power of the plating bath, and other aids can improve the situation somewhat, but the best approach is to eliminate or minimize holes with high aspect ratios during the product-design stage.

In plasma-coating processes, the part design will have considerable influence over the operating parameters of the coating-deposition equipment. Complex shapes, blind holes, fins, slots, and similar features will dictate that a high vacuum pressure, low part temperature, and light plasma density be used (Ref 11). The converse will be true for simple geometries. In plasma processing, consideration also must be given to heating of the part by the plasma itself. Some design features with thin cross sections and low mass, such as fins, louvers, and bosses will heat up faster than the bulk material in the part. For parts that have been heat treated, or otherwise finished to provide desirable mechanical properties, overheating could destroy those properties or at least change the values detrimentally. Reference 11 provides some examples of process and equipment modifications to avoid such problems during plasma nitriding. Reference 12 discusses the effect of part geometry on the growth of the nitride layer during ion nitriding and how coating uniformity can be improved for grooved surfaces. As in electroplating, decreasing the aspect ratio (depth of groove to width of groove) has a positive effect.

Design for Surface Finishing

Eric W. Brooman, Concurrent Technologies Corporation

Conclusions

From the above discussion, it may seem that design for surface finishing is an art rather than a science. Recently there has been a trend to modeling some of the coating processes in order to predict coating composition or distribution, and these models can be useful in avoiding bad design features. However, most of the principles in use and described in the article are derived from good common sense and have resulted from the cumulative experience gained by the finishing industry over many years.

Some finishing processes may impose their own special design limitations, but for many the general precepts outlined above should provide some guidance. Table 5 groups together the surface-treatment techniques discussed and a few others--not included here because of their similarity to these processes--that have similar design limitations associated with them. It cannot be stressed enough that product design is not a stand-alone activity, but must be integrated with other manufacturing operations to provide the requisite surface finish quality.

Table 5 Surface-finishing technologies grouped by similar design limitations

Design limitation	Surface-finishing process
Allow for fixturing/racking on nonsignificant surfaces	Painting, powder coating, sol-gel coating, solution coating, electroplating, electroless plating, anodizing, electrocoating, electropolymerization, electrophoretic plating, hot dipping, ion implantation, laser glazing, passivation, thermal spraying, electric arc spraying
Allow for electrical contact to be made on nonsignificant surfaces or use a conductive screen	Elecroplating, electropolishing, anodizing, electrocleaning, electrocoating, electropolymerization, electrophoretic plating, ion implantation, ion plating, powder coating
Surfaces must be accessible (preferably flat or simple, curved contours)	Grinding, polishing, lapping, burnishing, buffing, painting, electroplating, electroless plating, ion vapor deposition, cladding, ion implantation, hot dipping, slurry coating, laser glazing, mechanical plating, thermal spraying, electric arc spraying
Avoid intricate designs and surface features	Blasting, peening, brushing, burnishing, polishing, lapping, buffing, grinding, mechanical plating, hot dipping, cladding, cementation, slurry coating, mechanical plating, thermal spraying, electric arc spraying
Surfaces must be accessible to tools and withstand the local pressure and heat build up	Broaching, honing, grinding, brushing, burnishing, polishing, lapping
Avoid sharp corners, edges, and protuberances to prolong tool life	Blasting, lapping, brushing, burnishing, polishing, buffing, grinding
Allow for surface roughening to promote adhesion	Thermal spraying, electric arc spraying, sputtering, ion vapor deposition, ion plating, mechanical plating
Avoid thin cross sections (such as fins, louvers, walls) that could be distorted by heating or kinetic energy	Brushing, burnishing, grinding, lapping, solution coating, polishing, thermal stripping, hot dipping, cementation, laser glazing, mechanical plating, thermal spraying, electric arc spraying, diffusion coating
Avoid features that would shield the surface from beams or sprays (line-of-sight limited) unless	Chemical cleaning, chemical stripping, ion implantation, sputtering, ion plating, laser glazing, thermal spraying, electric arc spraying

multiple sources are used, or part is rotated/translated in beam or spray	
Avoid high aspect ratio holes and recesses, grooves, etc., that would not allow beams or sprays to reach bottom surfaces	Spray painting, ion plating, ion implantation, chemical cleaning, sputtering, laser glazing, thermal spraying, electric arc spraying
Avoid features that could trap air and prevent surface chemical reactions or coating from occurring or cause staining	Chemical milling, chemical cleaning, chemical stripping, etching, pickling, electroplating, spray painting, hot dipping, diffusion coating, electrocoating, sol-gel coating, solution coating, anodizing, electroless plating, electrophoretic plating, chemical vapor deposition, passivation
Avoid features (e.g., small recesses, blind holes, cavities) that would trap process chemicals or prevent satisfactory rinsing	Chemical milling, chemical cleaning, pickling, electrocleaning, chemical stripping, etching, electroplating, electroless plating, anodizing, mechanical plating, dipping (painting), conversion coating, solution coating, passivation, electrophoretic plating, electropolishing, sol-gel coating, electrocoating
Avoid recesses, holes, channels, and similar features that could trap materials	Blasting, peening, grinding, polishing, lapping, mechanical plating, thermal spraying, electric arc spraying
Provide good drainage or use drainage holes on nonsignificant surfaces to minimize carryover of process solutions	Chemical cleaning, chemical stripping, chemical milling, etching, electocleaning, pickling, electropolishing, conversion coating, electroplating, anodizing, electrophoretic plating, electroless plating, spray painting, sol-gel coating, solution coating, electrocoating, mechanical plating, passivation
Avoid, if possible, sharp edges and corners, ridges, blind holes, etc., that would prevent uniform coating thickness or metal removal	Chemical milling, etching, electropolishing, pickling, chemical stripping, sol-gel coating, solution coating, hot dipping, ion implantation, ion plating, thermal spraying, electric arc spraying
Avoid features that could trap evolved gases and cause staining or uneven attack	Chemical milling, etching, chemical cleaning, chemical stripping, electropolishing, pickling, electroplating, electrocleaning, electrocoating, anodizing, electroless plating, electrophoretic plating, passivation

- A
- **accuracy**
  - In measurement, the lack of deviation of a reading from a known input. A voltmeter that reads 10 V when subjected to 10 V is accurate. Accuracy is related to and governed by statistical bias .
- **activity-based costing (ABC)**
  - A cost-accounting approach that assumes that products incur costs by the activities they require for design, manufacture, and marketing. To implement ABC one must identify the major activities and their cost drivers, for example, hours of engineering services, number of production setups, etc. This is in contrast to conventional cost accounting where overhead costs are allocated solely through hours of direct labor or machine time.
- **activity diagram**
  - A diagram that lays out the tasks of a project in sequential order and shows when each must take place. Examples are Gantt charts and milestones charts.
- **adhesive**
  - A substance capable of holding materials together by surface attachment. Adhesive is a general term and includes, among others, cement, glue, mucilage, and paste. These terms are loosely used interchangeably.
- **advanced ceramics**
  - Ceramic materials that exhibit superior mechanical properties, corrosion/oxidation resistance, or electrical, optical, and/or magnetic properties. This term includes many monolithic ceramics as well as particulate-, whisker-, and fiber-reinforced glass, glass-ceramics, and ceramic-matrix composites. Also known as engineering, fine, or technical ceramics.
- **affinity diagram**
  - A diagram that organizes large number of ideas into their natural relationships. Often used as a follow up to group creativity activities such as brainstorming .
- **allotropic transformation**
  - The ability of a material to transform from one crystal structure to another. Closely synonymous with polymorphism.
- **amorphous material**
  - A material that lacks the long-range atomic periodicity that is characteristic of a crystalline solid.
- **anion**
  - A negatively charged ion that migrates toward the anode (positive electrode) under the influence of a potential gradient.
- **anisotropy**
  - The characteristics of exhibiting different values of a property in different directions with respect to a fixed reference system in the material.
- **assembly**
  - A collection of two or more parts. The assembly process is a series of joining processes (either permanent or nonpermanent) in which parts are oriented and added to the build. It is a mass-increasing process in which the macrogeometry is established by the positioning of the components.
- **assembly design**
  - The process of creating groups of parts that operate together.
- **assembly drawing**
  - An engineering drawing that shows how the individual elements of a product are to be put together, i.e., it shows the structure of the finished product. An assembly drawing usually includes a parts list to aid in the identification of the individual components.
- **austempering**
  - A heat treatment for ferrous alloys in which a part is quenched from the austenitizing temperature at a rate fast enough to avoid formation of ferrite or pearlite and then held at a temperature just above M_s until transformation to bainite is complete. Although designated as bainite in both austempered steel and austempered ductile iron, austempered steel consists of two-phase mixtures containing ferrite and carbide, while austempered ductile iron consists of two-phase mixtures containing ferrite and austenite.

- **austenite**
    - A high-temperature form of iron. In steel heat treating, the steel is heated into the austenite region before rapidly cooling (quenching).
- **austenite stabilizer**
    - An alloying element that when added to iron increases the region of the phase diagram in which austenite (face-centered cubic iron) is stable. Strong austenite stabilizers are carbon, nickel, and manganese.
- **availability**
    - In reliability theory, a measure of the degree to which an item is in operable and commitable state at the start of a mission, when the mission is called for at an unknown (random) time.
- **B**
- **bake-hardening steels**
    - Very-low carbon, fully ferritic steels (0.001% C) that are very formable, but harden during the paint-curing cycle. The strengthening results from the precipitation of titanium/niobium carbonitrides at 175 °C (350 °F).
- **benchmarking**
    - An improvement process in which a product design, process or service is measured against best-of-class operations in other companies.
- **bending moment**
    - The moments (force × distance) that tend to bend a beam in the plane of the loads.
- **benefit-cost analysis**
    - A form of economic analysis in which the economic benefits and costs of a project are determined with due allowance for the time value of money.
- **bias**
    - In statistics, the difference in a set of measurements between the mean value of a sample and the parameter from the large population that is used.
- **bill of materials**
    - A document used to track the parts in an assembly. It consists of the part number, part name, and quantity needed for the complete assembly. It may also contain information on procurement tracking or special assembly instructions. Also called the parts list.
- **blow molding**
    - A method of fabricating plastics in which a warm plastic parison (hollow tube) is placed between the two halves of a mold (cavity) and forced to assume the shape of that mold cavity by use of air pressure. The air pressure is introduced through the inside of the parison and forces the plastic against the surface of the mold, which defines the shape of the product.
- **blueprint**
    - The common shop term for a detailed engineering drawing giving dimensions and manufacturing details for a part. The term comes from an early printing process that gave a drawing with white lines on a blue background.
- **Boolean operation**
    - In solid modeling, three operators for combining sets of objects. The operators are union (+), difference (-), and intersection (*).
- **brainstorming**
    - A technique used by teams to generate ideas on a subject. Each person on the team is asked to think creatively and suggest as many ideas as possible. No criticism or discussion of the ideas is allowed until after the brainstorming session.
- **brazing**
    - A group of welding processes that join solid materials together by heating them to a suitable temperature and using a filler metal having a liquidus above 450 °C (840 °F) and below the solidus of the base materials. The filler metal is distributed between the closely fitted surfaces of the joint by capillary attraction.
- **break-even analysis**
    - An economic analysis in which costs are determined as a function of units of output or volume of production. The break-even point (minimum batch size) occurs at the number of units for which the revenues equal the total costs.
- **break-in**

- The early period of operating an engineering system, during which early equipment failures may be detected. With electronic systems this is usually known as burn-in. The break-in process is useful for weeding out design and manufacturing defects.

- **brittle material**
  - A material that exhibits brittleness, i.e., the tendency to fracture without first undergoing significant plastic deformation. Brittle materials exhibit low ductility.
- **buckling**
  - A form of mechanical instability in which failure occurs by unstable lateral deflection due to compressive forces applied to the structural element.
- **bulk forming**
  - Forming processes, such as extrusion, forging, rolling, and drawing, in which the input material is in billet, rod, or slab form and a considerable increase in surface-to-volume ratio in the formed part occurs under the action of largely compressive loading. Compare with sheet forming .
- **burden**
  - See overhead costs .
- **burn in**
  - See break-in .
- **C**
- **CAD/CAM**
  - An abbreviation for computer-aided design/computer-aided manufacturing.
- **Cartesian coordinate system**
  - A coordinate system in which the position of a point in a plane is determined by its distance and direction from the x and y axis, which are perpendicular to each other. In three dimensions a Cartesian coordinate system is defined by the x, y, and z axes.
- **casting**
  - (1) Metal object cast to the required shape by pouring of injecting liquid metal into a mold, as distinct from one shaped by a mechanical process. (2) Pouring molten metal into a mold to produce an object of desired shape. (3) Ceramic forming process in which a body slip is introduced into a porous mold, which absorbs sufficient water from the slip to produce a semirigid circle. See also polymer casting .
- **casting modulus**
  - A simplified approach to determining solidification time. The time is proportional to the square of the section modulus (the ratio of volume to surface area), known as Chvorinov's rule.
- **cation**
  - A positively charged ion that migrates through the electrolyte toward a cathode (negative electrode) under the influence of a potential gradient.
- **censored distribution**
  - A frequency distribution of observations that have either a lower or upper cutoff. For example, fatigue tests that are stopped unbroken after 10^6 cycles represent a censored frequency distribution.
- **central tendency of data**
  - In statistics this is described by the central limit theorem. This theorem states the fact that if one draws samples of size n from the population, and calculates the mean of these samples, the means will form a distribution which tends toward normality regardless of the form of the original sample distribution.
- **ceramic(s)**
  - Any of a class of inorganic nonmetallic products that are subjected to a high temperature during manufacture or use (high temperature usually means a temperature above a barely visible red, approximately 540 °C, or 1000 °F). Typically, but not exclusively, a ceramic is a metallic oxide, boride, carbide, or nitride, or a mixture of compound of such materials; that is, it includes anions that play important roles in atomic structures and properties. See also advanced ceramics .
- **Charpy test**
  - An impact test in which a V-notched, keyhole-notched, or U-notched specimen, supported at both ends, is struck behind the notch by a strike mounted at the lower end of a bar that can swing as a pendulum. The energy that is absorbed in fracture is calculated from the height to which the striker would have risen had there been no specimen and the height to which it actually rises after fracture of the specimen. Contrast with Izod test .
- **checklist**

- A tool used to ensure that all important steps or actions in an operation have been taken. Checklists contain those items that are important to the situation.

- **Chvorinov's rule**
  - See casting modulus .
- **coefficient of thermal expansion**
  - (1) Change in unit of length (or volume) accompanying a unit change of temperature, at a specified temperature. (2) The linear or volume expansion of a given material per degree rise of temperature, expressed at an arbitrary base temperature or as a more complicated equation applicable to a wide range of temperature.
- **coherent precipitate**
  - A crystalline precipitate that forms from solid solution with an orientation that maintains continuity between the crystal lattice of the precipitate and the lattice of the matrix, usually accompanied by some strain in both lattices. Because the lattices fit at the interface between precipitate and matrix, there is no discernible phase boundary.
- **colligative properties**
  - Properties of plastics based on the number of molecules present. Most important are certain solution properties extensively used in molecular weight characterization.
- **column**
  - A structural element that is long compared to its cross section. A column is often loaded axially in compression.
- **comminution**
  - The act of reducing a material to a powder, or reducing its particle size, by mechanical means (usually by grinding or milling).
- **commodity plastics**
  - Polymers such as polyethylene, polypropylene, and polyvinyl chloride that are used in high volume.
- **component**
  - A generic term for special-purpose parts, standard parts, and standard assemblies such as electric motors, transmissions, switch boxes, pulleys, etc.
- **composite material**
  - A combination of two or more materials (reinforcing elements, fillers, and composite matrix binder), differing in form or composition on a macroscale. The constituents retain their identities, i.e., they do not dissolve or merge completely into one another although they act in concert. Normally, the components can be physically identified and exhibit an interface between one another.
- **composite structure**
  - A structural member (such as a panel, plate, pipe, or other shape) that is built up by bonding together two or more distinct components, each of which may be made of a metal, alloy, nonmetal, or composite material . Examples of composite structures include: honeycomb panels, clad plate, electrical contacts, sleeve bearings, carbide-tipped drills or lathe tools, and weldments constructed of two or more different alloys.
- **compression molding**
  - A technique of thermoset molding in which the plastic molding compound (generally preheated) is placed in the heated open mold cavity, the mold is closed under pressure (usually in a hydraulic press), causing the material to flow and completely fill the cavity, and then pressure is held until the material has cured.
- **computational fluid dynamics (CFD)**
  - An area of computer-aided engineering devoted to the numerical solution and visualization of fluid-flow problems.
- **computer-aided design (CAD)**
  - Any design activity that involves the effective use of the computer to create or modify an engineering design. Often used synonymously with the more general term computer-aided engineering (CAE).
- **computer-aided materials selection system**
  - A computerized database of materials properties operated on by an appropriate knowledge base of decision rules through an expert system to select the most appropriate materials for an application. See also knowledge base .
- **computer-aided process planning (CAPP) program**

- A computer program that extracts the relevant geometric features from a CAD drawing and produces a process sequence or set of tool paths (for machining) that is optimal with respect to some criterion such as minimum processing time.

- **computer modeling**
  - The use of computers to simulate a physical system. Computers perform the numerical analysis and often graphically display the results.
- **concept selection method**
  - A group process of selecting a design concept or material in which the selection criteria and concepts are arranged in matrix form, and for each criterion the concepts are compared one at a time to a datum (reference) concept. Often called the Pugh concept selection method, after its originator, Stuart Pugh.
- **conceptual design**
  - The initial stage of the engineering design process in which a physical concept of the product is developed. The physical concept includes the principles by which the product will work and an abstract physical embodiment that will employ the principles to achieve the desired functions.
- **concurrent engineering**
  - A style of product design and development that is done by concurrently utilizing all of the relevant information in making each decision. It replaces a sequential approach to product development in which one type of information was predominant in making each sequential decision. Concurrent engineering is carried out by a multifunctional team that integrates the specialties or functions needed to solve the problem. Sometimes called simultaneous engineering.
- **configuration design**
  - The stage after conceptual design in the engineering design process in which the features of a part and their arrangement and connectivity are determined. Qualitative reasoning based on fundamental principles is used to make decisions between alternatives. A sketch of the part and preliminary decisions on material selection and manufacturing methods are made in this stage. Final dimensions and tolerances are not determined in this stage. Also known as embodiment design.
- **constitutive equation**
  - A mathematical relationship that describes the flow stress of a material in terms of the plastic strain, the strain rate, and temperature.
- **constraint modeling**
  - A form of computer modeling in which constraints are used to create a set of rules that control how changes are made to a group of geometric elements (lines, arcs, form features, etc.). These rules are typically embodied in a set of equations. Constraint models are defined as either parametric or variational.
- **continuum mechanics**
  - The science of mathematically describing the behavior of continuous media. The same basic approach can apply to descriptions of stress, heat, mass, and momentum transfer.
- **controlled rolling**
  - A hot-rolling process in which the temperature of the steel is closely controlled, particularly during the final rolling passes, to produce a fine-grain microstructure.
- **convergent thinking**
  - See vertical thinking .
- **conversion coating**
  - A coating consisting of a compound of the surface metal, produced by chemical or electrochemical treatments of the metal. Examples include chromate coatings on zinc, cadmium, magnesium, and aluminum, and oxide and phosphate coatings on steel.
- **copolymer**
  - A long-chain molecule formed by the reaction of two or more dissimilar monomers. See also polymer .
- **corrosion**
  - The chemical or electrochemical reaction between a material, usually a metal, and its environment that produces a deterioration of the material and its properties.
- **cost allocation**
  - In design, the process by which the components of a design are assigned a target cost.
- **covalent bond**
  - A bond in which two atoms share a pair of electrons. Contrast with ionic bond .

- **crack opening displacement (COD)**
  - On a K_{Ic} specimen, the opening displacement of the notched surfaces at the notch and in the direction perpendicular to the plane of the notch and the crack. The displacement at the tip is called the crack tip opening displacement (CTOD); at the mouth, it is called the crack mouth opening displacement (CMOD). See also stress-intensity factor for definition of K_{Ic}.
- **creative process**
  - A total problem resolution process that yields a truly novel solution to the problem. A creative solution requires both vertical thinking (convergent thinking) and lateral thinking (divergent thinking).
- **creep**
  - Time-dependent strain occurring under stress. The creep strain occurring at a diminishing rate is called primary creep; that occurring at a minimum and almost constant rate, secondary creep; and that occurring at an accelerating rate, tertiary creep.
- **creep rupture**
  - Failure at elevated temperature under load (stress) conditions greater than found in creep tests so that rupture occurs, generally at shorter times and larger deformations than for a creep test.
- **criterion function**
  - See objective function .
- **cross-functional team**
  - A team whose members are from several units of the organization that interface with, and need input from, one another.
- **cross linking**
  - With thermosetting and certain thermoplastic polymers, the setting up of chemical links between the molecular chains. When extensive, as in most thermosetting resins, cross linking makes an infusible supermolecule of all the chains. In rubbers, the cross linking is just enough to join all molecules into a network.
- **crystalline**
  - That form of a substance comprised predominantly of (one or more) crystals, as opposed to glassy or amphorous.
- **crystalline defects**
  - The deviations from a perfect three-dimensional atomic packing that are responsible for much of the structure-sensitive properties of materials. Crystal defects can be point defects (vacancies), line defects (dislocations), or surface defects (grain boundaries).
- **cumulative distribution function (CDF)**
  - A frequency distribution arranged to give the number of observations that are less than given values. 100% of the observations will be less than the largest class interval of the observations.
- **customer**
  - The recipient or beneficiary of the output of an organization's work effort or the purchaser of a product or service. A customer may be either external or internal to the organization. A chief objective of total quality management is to exceed customer expectations, each and every time.
- **customer delight**
  - The result of delivering a product or service that exceeds customer expectations.
- **customer importance rating**
  - An indication of the priority of importance the customer places on a certain want. Determined by dividing the number of times customers mention this need by the number of subjects interviewed or surveyed.
- **cycle time**
  - The time to produce a part. Cycle time is the reciprocal of production rate.
- **D**
- **damage**
  - Impairment of the useful life of a part.
- **damage tolerance**
  - The ability of a component to resist failure due to the presence of flaws, cracks, or other structural damage for a specified period of usage.
- **data associativity**
  - The ability of a computer-aided engineering system to share design information among a variety of computer-based applications (such as design, drafting, and numerical-controlled machining) without each application having to translate or transfer the data. Associativity also requires that

applications can recognize when geometry or other information has been changed so that the application can adjust its own data to these changes.

- **database**
  - A collection of specific information, such as alloy compositions or mechanical properties. Many databases are accessible through on-line connections or with a CD-ROM.
- **data integration**
  - See data associativity .
- **decision matrix**
  - A formalized process by which design concepts or materials are ranked prior to a selection decision.
- **decomposition**
  - A general term used in design to describe the process of breaking the product into subassemblies, or smaller units; for example, the automobile can be decomposed into the engine, drive train, chassis, etc. Decomposition can be done in terms of physical embodiments, as above, or in terms of functions that the design must perform.
- **defect**
  - The nonfulfillment of a product or service with respect to an intended requirement or reasonable expectation of use, including safety considerations. There are four classes of defects: (1) very serious, leading directly to severe injury or catastrophic economic loss; (2) serious, leading directly to significant injury or significant economic loss; (3) major, related to major problems with respect to intended normal or reasonable foreseeable use; (4) minor, related to minor problems with respect to intended normal or reasonably foreseeable use.
- **deflection temperature under load (DTUL)**
  - See heat distortion temperature (HDT).
- **deformation curve**
  - See stress-strain curve .
- **deformation processing**
  - A class of manufacturing operation that involves changing the shape of a workpiece by plastic deformation through the application of a compressive force. Often carried out at elevated temperature.
- **delamination**
  - The separation of layers in a laminate or composite material because of failure of the matrix, either in the matrix itself or at the interface between the matrix and the fiber.
- **design changes**
  - Changes in a design that come about because of (1) mistakes on the drawings, (2) design- or manufacturing-related problems, or (3) product improvements.
- **design code**
  - A set of rules or regulations that tell the designer what to do and when and under what circumstances. While codes are often developed by technical or professional groups, they often are adopted by governmental jurisdictions and become legal requirements. Examples are the building code for the structural safety of buildings and the fire code.
- **design constraint**
  - A design parameter (variable) that is required to fall within a fixed range of values.
- **design defect**
  - Any aspect of a design or product that causes it to fail to perform as safely or reliably as an ordinary consumer would expect. See also defect .
- **design features**
  - The elements that comprise a part, such as walls, holes, and grooves, and the solid elements, such as rods, cubes, and tubes.
- **design for assembly (DFA)**
  - A methodology for examining the assembled parts of a product in terms of the time and cost for assembly of each part. The overriding strategy is to produce an acceptable design with the minimum number of parts.
- **design for disassembly (DFD)**
  - A methodology for designing a product so that it can be economically disassembled and the material from which the individual parts are made can be recovered and reused.
- **design for the environment (DFE)**

- A design methodology in which environmental factors are considered of equal importance to performance factors. Sometimes called green design.

- **design for function and fit**
  - An expression that exemplifies the two central rules of design: (1) first and foremost, the design must perform the function for which it is intended; (2) the design must be designed to tolerances appropriate to the application.
- **design for manufacture, design for manufacturability (DFM)**
  - An approach toward integrating the product and process concepts so that the best match is made between product and process requirements. DFM includes detailed examination of the design so that it is most easily and inexpensively manufactured by the intended process.
- **design for "X" (DFX)**
  - A catch phrase that describes the understanding that engineering designs increasingly must be consciously designed for factors other than function and tolerances. These issues include design for assembly (DFA), design for manufacture (DFM), and design for installation, maintenance, safety, disposal, etc.
- **design intent**
  - A general term used with respect to describing and documenting the aspects of some part of the design that are crucial to the success of the design.
- **design layout**
  - An engineering drawing, either two-dimensional or three-dimensional, that shows the individual parts of a system in relationship to one another. An assembly drawing often serves the same purpose.
- **design optimization**
  - See optimization .
- **design of experiments (DOE)**
  - A methodology involving statistically designed experiments in which the character and sequence of individual experiments are planned in advance so that data are taken in a way that will provide the most unbiased and precise results commensurate with the available time and money. The chief classes of statistically designed experiments are: (1) blocking designs to remove the effect of background variables from the experimental error, (2) factorial designs, in which all levels of each factor in an experiment are combined with all levels of every other factor, and (3) response surface designs, which determine the empirical relation between the factors (independent variables) and the response (performance variable).
- **design parameters**
  - A term used to describe the chief variables of a design problem. Sometimes called the design attributes or design characteristics. Design parameters define the object or process that is being designed and thus provide a means for changing the design to improve performance.
- **design performance measures**
  - Performance measures that are functions of the design parameters and are used to quantify the effectiveness of a given design. Performance measures often are grouped into an objective function and the problem constraints.
- **design review**
  - A group examination and discussion intended to ensure that the design, and all of its components, will meet customer requirements.
- **design rules**
  - A set of guidelines developed from experience that tell the designer how to make decisions in typical situations. Often these rules suggest how to design to minimize cost of manufacture. For example: "Try to design the part so it can be machined on one machine tool only."
- **design sensitivity**
  - See sensitivity analysis .
- **design standards**
  - Agreed-upon descriptions of best solutions to repetitive design problems, arrived at by general consent of an appropriate broad-based technical group. While standards do not have the force of law, they often are incorporated into a design code .
- **design team**
  - A multi-functional group that contains not only the technical expertise to design the product but also expertise in manufacturing and marketing.
- **detail design**

- The final phase of design in which all information on materials, manufacturing processes, dimensions, and tolerances are supplied. The output of this design phase is a complete set of drawings and product specifications. Also known as parametric design.

- **detail drawing**
  - An engineering drawing that provides sufficient information to make the part. This information usually includes plan, front, and side views; auxiliary views and sections through the part; dimensions; and tolerances.
- **die swell**
  - The expansion of the polymer melt that occurs as the extruded melt exits the die. This is due to the aligned polymer chains being released from the confines of the die and returning to their random coil configuration.
- **dimensional management**
  - An engineering design methodology that aims to absorb as much variation as possible without affecting the function of the product. It does this through the optimal selection of datums, feature controls, assembly methods, and assembly sequence. It differs from the conventional practice of assigning tolerances to drawings prior to release in that it is more systematic and more global in outlook and employs three-dimensional tolerance analysis CAE tools.
- **directionally solidified (DS) eutectic composite**
  - A metal-matrix composite material produced by directional solidification of the eutectic composition of an alloy.
- **directional solidification**
  - Controlled solidification of molten metal in a casting so as to provide feed metal to the solidifying front of the casting. Usually this results in the metal solidifying in a preferred direction. In the limit, the solidification can be controlled to grow as a single grain (single crystal casting).
- **dislocation**
  - A linear imperfection in a crystalline array of atoms. Two basic types are recognized: (1) an edge dislocation corresponds to the row of mismatched atoms along the edge formed by an extra, partial plane of atoms within the body of a crystal; (2) a screw dislocation corresponds to the axis of a spiral structure in a crystal, characterized by a distortion that joins normally parallel planes together to form a continuous helical ramp (with a pitch of one interplanar distance) winding about the dislocation. Most prevalent is the so-called mixed dislocation, which is any combination of an edge dislocation and a screw dislocation.
- **dislocation density**
  - The total length of dislocation lines per unit volume, or the number of dislocation lines that cut through a unit cross-sectional area.
- **dispersion strengthening**
  - The strengthening of a metal or alloy by incorporating chemically stable submicron size particles of a nonmetallic phase that impede dislocation movement at elevated temperature.
- **divergent thinking**
  - See lateral thinking .
- **Dominic method**
  - A qualitative method for evaluating and choosing between alternative design concepts or materials. The method uses an evaluation table in which the evaluation criteria are grouped according to priority (high, moderate, low), and the alternative solutions are ranked as excellent, good, fair, poor, or unacceptable.
- **draft**
  - An angle or taper on the surface of a pattern, core box, punch, or die (or of the parts made with them) that facilitates removal of the parts from a mold or die cavity, or a core from a casting.
- **drape**
  - The ability of a polymer sheet or composite sheet to conform to the shape of the mold.
- **drawing**
  - A term used for a variety of forming operations, such as deep drawing a sheet metal blank; redrawing a tubular part; and drawing rod, wire, and tube. The usual drawing process with regard to sheet metal working in a press is a method for producing a cuplike form from a sheet metal disk by holding it firmly between blankholding surfaces to prevent the formation of wrinkles while the punch travel produces the required shape.
- **ductility**
  - The ability of a material to deform plastically without fracturing.

- **ductile-to-brittle transition temperature**
  - See transition temperature .
- **dynamic recovery**
  - A process occurring in hot working of metals in which a fine subgrain structure forms within the elongated grains due to annihilation of dislocations due to easy cross slip and climb. It results in a lowering of the flow stress. Dynamic recovery, as opposed to dynamic recrystallization that occurs in hot working, occurs in metals of high stacking fault energy such as aluminum, α iron, and most bcc metals.
- **dynamic strain aging**
  - A behavior in metals in which solute atoms are sufficiently mobile to move toward and interact with dislocations. This results in strengthening over a specific range of elevated temperature and strain rate.
- **E**
- **economy of scale**
  - Variation of cost with production volume. Usually, unit cost decreases with increasing volume.
- **economy of scope**
  - The concept that value is created more by the ability to create products with very many functions or variations from a common theme than by reducing the unit cost from increased volume of production.
- **elasticity**
  - The property of a material by virtue of which deformation caused by stress disappears upon removal of the stress. A perfectly elastic body completely recovers it original shape and dimensions after release of stress.
- **elastomer**
  - Any elastic, rubberlike substance, such as natural or synthetic rubber.
- **electrical permittivity**
  - The material property that directly relates the voltage and geometry of the system to the electrical field energy. Magnetic permeability is the magnetic field energy counterpart.
- **electrical resistivity**
  - The electrical resistance offered by a material to the flow of current, times the cross-sectional area of current flow and per unit length of current path; the reciprocal of the conductivity. Also called resistivity or specific resistance.
- **electronegativity**
  - The relative tendency of an atom to attract electrons. Carbon, the basic building block of polymers, is neutral in this respect with a Pauling electronegativity of 2.5. Metallic atoms on the left side of the periodic table have a propensity to lose electrons when forming covalent bonds, and their electronegativities are less than 2.5. The atoms on the right side of the periodic table tend to gain electrons, and their electronegativities tend to be greater than 2.5.
- **electrophoretic paint (e-coat)**
  - A paint that is applied by electrophoresis, in which colloidal charged particles are transported within an electric field.
- **elongation**
  - (1) A term used in mechanical testing to describe the amount of extension of a test piece when stressed. (2) In tensile testing, the increase in the gage length, measured after fracture of the specimen within the gage length, usually expressed as a percentage of the original gage length.
- **embodiment design**
  - See configuration design .
- **end-grain attack**
  - Preferential corrosive attack of grains exposed by cutting through the cross section of a rod or plate.
- **endurance limit**
  - See fatigue limit .
- **engineering design specification**
  - A detailed description of the intended and unintended uses that a product will be put to, a list of any special features required or desired, and a detailed list of the functional requirements with qualitative or quantitative goals and limits for each. Also known as product design specification.
- **engineering plastics**

- A general term covering all plastics, with or without fillers or reinforcements, that have mechanical, chemical, and thermal properties suitable for use as construction materials, machine components, and chemical processing equipment components. Included are acrylonitrile-butadiene-styrene, acetal, acrylic, fluorocarbon, nylon, phenoxy, polybutylene, polyaryl ether, polycarbonate, polyether (chlorinated), polyether sulfone, polyphenylene oxide, polysulfone, polyimide, rigid polyvinyl chloride, polyphenylene sulfide, thermoplastic urethane elastomers, and many other reinforced plastics.

- **environmentally assisted cracking**
  - Brittle fracture of a normally ductile material in which the corrosive effect of the environment is a causative factor. Environmental cracking is a general term that includes corrosion fatigue, high-temperature hydrogen attack, hydrogen blistering, hydrogen embrittlement, liquid metal embrittlement, solid metal embrittlement, stress-corrosion cracking, and sulfide stress cracking.
- **environmental impact assessment**
  - A system-wide determination of the multiple impacts that an engineering product has on the environment.
- **erosion**
  - (1) Loss of material from a solid surface due to relative motion in contact with a fluid that contains solid particles. Erosion in which the relative motion of particles is nearly parallel to the solid surface is called abrasive erosion. Erosion in which the relative motion of the solid particles is nearly normal to the solid surface is called impingement erosion or impact erosion. (2) Progressive loss of original material from a solid surface due to mechanical interaction between that surface and a fluid, a multicomponent fluid, and impinging liquid, or solid particles. (3) Loss of material from the surface of an electrical contact due to an electrical discharge (arcing).
- **evaluation of property data**
  - The process of establishing the accuracy and integrity of property data by appraisal of the data presented, assessment of the experimental technique and its associated errors, and checking for consistency of values and comparison with other experimental or theoretical values.
- **event tree analysis (ETA)**
  - A binary logic tree for tracing all the possible consequences of an event. Unlike the fault tree, the event tree starts with an initiating event and traces all possible consequences. See also fault tree analysis .
- **expert system**
  - A computer-based system that captures the knowledge of experts through the integration of databases and knowledge bases using search and logic deduction algorithms.
- **extrusion (ceramics)**
  - The process of forcing a mixture of plastic binder and ceramic powder through the opening(s) of a die at relatively high pressure. The material may thus be compacted and emerges in elongated cylindrical or ribbon (or wire, etc.) form having the cross section of the die opening. Ordinarily followed by drying, curing, activating, or firing.
- **extrusion (metals)**
  - The conversion of an ingot or billet into long lengths by forcing metal to flow through a die orifice. The cross section of the extrusion may be circular or highly irregular and specific in shape.
- **extrusion (plastics)**
  - Compacting a plastic material into a powder or granules in a uniform melt and forcing it through an orifice in a more or less continuous fashion to yield a desired shape. While held in the desired shape, the melt must be cooled to a solid state.
- **F**
- **factor of safety**
  - The ratio of the material strength to the computed stress. The factor of safety can vary from about 1.3, where component performance is well known and material properties show little variability, to 3 or 4 for an untried material or where stresses or environment are uncertain.
- **fail-safe design**
  - A design that seeks to ensure that a failure will not affect the product or change it to a state in which injury or damage will occur.
- **failure mode and effect analysis (FMEA)**
  - A systematic, detailed method of analysis of the malfunctions or defects that can be produced in the components of an engineering system. The analysis examines each potential failure mode to

assess the reliability of the system elements and to ascertain the consequences of the failure upon the entire system.

- **failure mode, effect, and criticality analysis (FMECA)**
    - An extension of FMEA in which the criticality of each assembly is examined and the components and assemblies to which special attention should be given are identified.
- **fatigue**
    - The phenomenon leading to fracture under repeated or fluctuating stresses having a maximum value less than the ultimate tensile strength of the material. Fatigue failure generally occurs at loads that applied statically would produce little perceptible effect. Fatigue fractures are progressive, beginning as minute cracks that grow under the action of the fluctuating stress.
- **fatigue limit**
    - The maximum cyclic stress that a material can withstand for an infinitely large number of stress cycles. Also called endurance limit.
- **fatigue-strength reduction factor**
    - The ratio of the fatigue strength of a member or specimen with no stress concentration to the fatigue strength with stress concentration. This factor has no meaning unless the stress range and the shape, size, and material of the member or specimen are stated.
- **fault hazard analysis (FHA)**
    - A qualitative analysis of design hazards other than malfunctions. FMEA, FMECA, and FTA consider only malfunctions.
- **fault tree analysis (FTA)**
    - An analysis method that provides a systematic description of the combinations of possible occurrences in a system that can result in failure. It is a graphical representation of the Boolean logic that relates to the output (top) event.
- **features**
    - In computer modeling, higher level constructs (than points, curves, and surfaces) that allow designers to work more naturally with geometries such as slots, through holes, bosses, etc. Form features such as these allow designers to add relatively complex yet common shapes without having to apply Boolean operations on blocks and other shapes.
- **ferrite stabilizer**
    - An alloying element that, when added to iron, increases the region of the phase diagram in which ferrite is the stable phase. The strongest ferrite stabilizers are silicon, chromium, and molybdenum.
- **filament winding**
    - A process for fabricating a reinforced plastic or composite structure in which continuous reinforcements (filament, wire, yarn, tape, and the like), either previously impregnated with a matrix material or impregnated during the winding, are placed over a rotating and removable form or mandrel in a prescribed way to meet certain stress conditions. Generally the shape is a surface of revolution and may or may not include end closures. When the required number of layers is applied, the wound form is cured and the mandrel is removed.
- **finite element analysis**
    - See finite element modeling (FEM).
- **finite element modeling (FEM)**
    - A numerical technique in which the analysis of a complex part is represented by a mesh of elements interconnected at node points. The coordinates of the nodes are combined with the elastic properties of the material to produce a stiffness matrix, and this matrix is combined with the applied loads to determine the deflections at the nodes, and hence, the stresses. All of the above is done with special FEM software. The FEM approach also may be used to solve other field problems in heat transfer, fluid flow, acoustics, etc. Also known as finite element analysis (FEA).
- **firing**
    - The controlled heat treatment of ceramic ware in a kiln or furnace, during the process of manufacture, to develop the desired properties.
- **fixed costs**
    - Those costs that do not increase with the volume of production, e.g., the cost of capital equipment, overhead labor costs, etc. See also variable costs .
- **fixture**

    - A device for holding a part to be joined, assembled, or machined. Often, two or more parts are held by the fixture in proper relation to each other.
- **flanging**
    - Bending a sheet along a curved line.
- **flexural modulus**
    - The ratio, within the elastic limit, of the applied stress on a reinforced plastic test specimen in flexure to the corresponding strain in the outermost fibers of the specimen.
- **flexural strength**
    - A property of solid material that indicates its ability to withstand a flexural or transverse load.
- **flow stress**
    - The stress required to produce plastic deformation in a solid material.
- **forging**
    - The process of working metal to a desired shape by impact or pressure in hammers, forging machines (upsetters), presses, rolls, and related forming equipment. Forging hammers, counterblow equipment, and high-energy-rate forging machines apply impact to the workpiece, while most other types of forging equipment apply squeeze pressure in shaping the stock. Some metals can be forged at room temperature, but most are made more plastic for forging by heating.
- **formability**
    - The ease with which a material can be shaped through plastic deformation. Closely related to the term workability. In general practice, formability refers to the shaping of sheet materials while workability refers to shaping by bulk forming processes such as forging or extrusion.
- **forming**
    - (1) Making a change, with the exception of shearing or blanking, in the shape or contour of a metal part without intentionally altering its thickness. (2) The plastic deformation of a billet or a blanked sheet between tools (dies) to obtain the final configuration. Metal forming processes are typically classified as bulk forming and sheet forming . Also referred to as metalworking. (3) A process in which the shape of plastic pieces such as sheets, rods, or tubes is changed to a desired configuration. The use of the term forming in plastics technology does not include such operations as molding, casting, or extrusion, in which shapes or pieces are made from molding materials or liquids.
- **forming limit diagram (FLD)**
    - A diagram in which the major strains at the onset of necking in sheet metal are plotted vertically and the corresponding minor strains are plotted horizontally. The onset-of-failure line divides all possible strain combinations into two zones: the safe zone (in which failure during forming is not expected) and the failure zone (in which failure during forming is expected).
- **fracture**
    - (1) The irregular surface produced when a piece of metal is broken. (2) In composites, the separation of a body. Defined both as rupture of the surface without complete separation of the laminate and as complete separation of a body because of external or internal forces. Fractures in continuous-fiber-reinforced composites can be divided into three basic fracture types: intralaminar, interlaminar, and translaminar. Translaminar fractures are those oriented transverse to the laminated plane in which conditions of fiber fracture are generated. Interlaminar fracture, on the other hand, describes failures oriented between plies, whereas intralaminar fractures are those located internally within a ply.
- **fracture toughness**
    - A generic term for measures of resistance to extension of a crack. The term is sometimes restricted to results of fracture mechanics tests, which are directly applicable in fracture control. However, the term commonly includes results from simple tests of notched or precracked specimens not based on fracture mechanics analysis. Results from tests of the latter type are often useful for fracture control, based on either service experience or empirical correlations with fracture mechanics tests. See also stress-intensity factor .
- **function analysis**
    - A technique used in the discipline of value analysis that focuses on the reason-for-being of each element of the product.
- **functional decomposition**
    - A hierarchical breakdown of a design or product into the basic functions that must be achieved. This is done by asking the question how? For example, the basic function of a copier is to make

copies. Asking how leads to the next level of functions: feed paper, make marks, handle documents, etc. Each function is stated by a verb and a noun.

- **functional requirements**
  - Those elements of the design that describe its performance behavior, including its human interface and the environment in which it must function.
- **fuzzy logic**
  - The use of fuzzy sets in the representation and manipulation of vague information for the purpose of making decisions or taking actions. Fuzzy logic enables computers to make decisions based on information that is not clearly defined.
- **G**
- **galvanic corrosion**
  - Corrosion associated with the current of a galvanic cell consisting of two dissimilar conductors in an electrolyte or two similar conductors in dissimilar electrolytes. Where the two dissimilar metals are in contact, the resulting reaction is referred to as couple action.
- **gate**
  - In a metal casting, the portion of the runner in a mold through which molten metal enters the cavity. In injection molding and transfer molding of plastics, the gate is the orifice through which the viscous melt enters the mold cavity.
- **geometric dimensioning and tolerancing (GD&T)**
  - A comprehensive system of standards for the location of features on an engineering drawing and describing their tolerances with respect to form, profile, orientation, and runout.
- **glass**
  - An amorphous solid made by fusing silica (SiO_2) with a basic oxide. Its characteristic room-temperature properties are transparency to light, hardness and rigidity, and resistance to weathering and most chemicals.
- **glass ceramics**
  - A family of fine-grained crystalline materials made by a process of controlled crystallization from special glass compositions containing nucleating agents.
- **glass transition temperature (T_g)**
  - The temperature at which an amorphous polymer (or the amorphous regions in a partially crystalline polymer) changes from a hard and relatively brittle condition to a viscous or rubbery condition. In this temperature region, many physical properties, such as hardness, brittleness, thermal expansion, and specific heat, undergo significant, rapid changes.
- **glaze**
  - A continuous adherent layer of glass applied to the surface of a ceramic body as a suspension of ingredients and then fired to yield a hard, nonabsorbent surface layer.
- **go/no-go decision**
  - A type of decision where an absolute lower (or upper) limit has been established as necessary for the functioning of the design. All materials or components that do not exceed the lower limit specification are rejected (no-go), while those that do are accepted and subjected to further screening. See screening property .
- **grain boundary**
  - A narrow zone in a metal or ceramic corresponding to the transition from one crystallographic orientation to another, thus separating one grain from another; the atoms in each grain are arranged in an orderly pattern.
- **granulation**
  - The intentional agglomeration of fine ceramic particles into larger clusters in order to improve such properties as bulk density and powder flowability and to cause a reduction of dusting losses.
- **granulated metal**
  - Small pellets produced by pouring liquid metal through a screen or by dropping it onto a revolving disk and, in both instances, chilling with water.
- **green design**
  - See design for the environment .
- **green strength**
  - The strength of a powdered material in the compacted state before sintering or firing. Green strength must be sufficient to allow the part to be removed from the compaction die and handled before sintering.
- **group technology**

- An approach to design and manufacturing that seeks to reduce manufacturing system information content by identifying and exploiting the sameness or similarity of parts based on their geometrical shape and/or similarities in their production process.

- **guided iteration**
  - A general problem-solving methodology applicable to engineering design. The steps in this process are: formulation of the problem, generation of alternative solutions, and evaluation of the alternatives. If none of the alternatives is acceptable, the process continues with redesign, guided by the results of the evaluation.
- **Guinier-Preston (G-P) zone**
  - A small precipitation domain in a supersaturated metallic solid solution. A G-P zone has no well-defined crystalline structure of its own and contains an abnormally high concentration of solute atoms. The formation of G-P zones constitutes the first stage of precipitation and is usually accompanied by a change in properties of the solid solution in which they occur.
- **H**
- **Hall-Petch relationship**
  - A general relationship for metals that shows that the yield strength is linearly related to the reciprocal of the square root of the grain diameter.
- **hard constraint**
  - A design requirement that cannot be relaxed, i.e., a must requirement.
- **hardfacing alloys**
  - Wear-resistant materials available as bare welding rod, flux-coated rod, long-length solid wires, long-length tubular wires, or powders that are deposited by hardfacing. Hardfacing materials include a wide variety of alloys, ceramics, and combinations of these materials. Conventional hardfacing alloys are normally classified as steels or low-alloy ferrous materials, chromium white irons, high-alloy ferrous materials, carbides, nickel-base alloys, or cobalt-base alloys.
- **hardness**
  - A measure of the resistance of a material to surface indentation or abrasion; may be thought of as a function of the stress required to produce some specified type of surface deformation. There is no absolute scale for hardness; therefore, to express hardness quantitatively, each type of test has its own scale of arbitrarily defined hardness. Indentation hardness can be measured by Brinell, Rockwell, Vickers, Knoop, and Scleroscope hardness tests.
- **hazard**
  - Any aspect of technology or human activity that produces risk, i.e., the potential for harm or damage to people, property, or the environment.
- **heat-affected zone (HAZ)**
  - That portion of the base metal that was not melted during brazing, cutting, or welding, but whose microstructure and mechanical properties were altered by the heat.
- **heat distortion temperature (HDT)**
  - The temperature at which a bend specimen made from a plastic material deflects a specified amount under a fixed static load. This temperature is sometimes called the deflection temperature under load (DTUL).
- **high-cycle fatigue**
  - Fatigue that occurs at relatively large numbers of cycles. The arbitrary, but commonly accepted, dividing line between high-cycle fatigue and low-cycle fatigue is considered to be about 10^4 to 10^5 cycles. In practice, this distinction is made by determining whether the dominant component of the strain imposed during cyclic loading is elastic (high cycle) or plastic (low cycle), which in turn depends on the properties of the metal and on the magnitude of the nominal stress.
- **Hooke's law**
  - A generalization applicable to all solid material, which states that stress is directly proportional to strain and is expressed as:

$$\frac{\text{Stress}}{\text{Strain}} = \frac{\sigma}{\varepsilon} = \text{constant} = E$$

  - where *E* is the modulus of elasticity (Young's modulus). The constant relationship between stress and strain applies only below the proportional limit. See also modulus of elasticity .
- **hot isostatic pressing (HIP)**

- (1) A process for simultaneously heating and forming a compact in which the powder is contained in a sealed flexible sheet metal or glass enclosure and the so-contained powder is subjected to equal pressure from all directions at a temperature high enough to permit plastic deformation and sintering to take place. (2) A process that subjects a component (casting, powder forgings, etc.) to both elevated temperature and isostatic gas pressure in an autoclave. The most widely used pressurizing gas is argon. When castings are hot isostatically pressed, the simultaneous application of heat and pressure virtually eliminates internal voids and microporosity through a combination of plastic deformation, creep, and diffusion.

- **house of quality**
  - See quality function deployment .
- **hygrothermal effect**
  - Change in properties and shape change of a material (particularly plastics and polymer matrix composites) due to moisture absorption and temperature change.
- **hypereutectic alloy**
  - In an alloy system exhibiting a eutectic, any alloy whose composition has an excess of alloying element compared with the eutectic composition and whose equilibrium microstructure contains some eutectic structure.
- **hysteresis loop**
  - In dynamic mechanical measurement, the closed curve representing successive stress-strain status of a material during a deformation cycle.
- **I**
- **impact strength**
  - A measure of the resiliency or toughness of a solid. The maximum force or energy of a blow (given by a fixed procedure) that can be withstood without fracture, as opposed to fracture strength under a steady applied force.
- **inclusion**
  - (1) A physical and mechanical discontinuity occurring within a material or part, usually consisting of solid, encapsulated foreign material. Inclusions are often capable of transmitting some structural stresses and energy fields, but to a noticeably different degree than from the parent material.
- **indirect costs**
  - See overhead costs .
- **industrial design**
  - The first broadly functional description of a product with emphasis on visual and aesthetic features (shape, color, texture).
- **Initial Graphics Exchange Standard (IGES)**
  - A protocol for transferring graphics data between CAD systems.
- **injection molding (ceramics)**
  - A process for forming ceramic articles in which a granular ceramic-binder mix is heated until softened and then forced into a mold cavity, where it cools and resolidifies to produce a part of the desired shape.
- **injection molding (metals)**
  - A process similar to plastic injection molding using a plastic-coated metal powder of fine particle size ($\sim$10 μm).
- **injection molding (plastics)**
  - Method of forming a plastic to the desired shape by forcing the heat-softened plastic into a relatively cool cavity under pressure.
- **inoculant**
  - Materials that, when added to molten metal, modify the structure and thus change the physical and mechanical properties to a degree not explained on the basis of the change in composition resulting from their use. Ferrosilicon-base alloys are commonly used to inoculate gray irons and ductile irons.
- **integrated product development team (IPDT)**
  - A flexible, collaborative, multidisciplinary team assigned with the responsibility of developing a product and the process to manufacture it. In addition to design and manufacturing engineers with the appropriate technical backgrounds, the team should include members with financial, marketing, field service, and purchasing experience.
- **intellectual property**

- Knowledge-based property, usually represented by patents, copyrights, trademarks, or trade secrets.
- **interlock**
  - A device provided to ensure that an event does not occur inadvertently or that a specific sequence of events is followed where the sequence is important or necessary and a wrong sequence of events could cause a mishap.
- **interstitial-free steels**
  - Steels where carbon and nitrogen are removed in the steelmaking process to very low levels, and any remaining interstitial carbon and nitrogen is tied up with small amounts of alloying elements that form carbides and nitrides, i.e., titanium and niobium. Although these steels have low strength they exhibit exceptional formability.
- **ionic bond**
  - (1) A type of chemical bonding in which one or more electrons are transferred completely from one atom to another, thus converting the neutral atoms into electrically charged ions. These ions are approximately spherical and attract each other because of their opposite charges. (2) A primary bond arising from the electrostatic attraction between two oppositely charged ions. Contrast with covalent bond .
- **ISO 9000**
  - A set of five individual but related international standards on quality management and quality assurance . The standards were developed by the International Organization for Standardization (ISO).
- **ISO 14000**
  - A generic international standard for environmental management systems.
- **isothermal transformation (IT) diagram**
  - A diagram that shows the isothermal time required for transformation of austenite to begin and to finish as a function of temperature.
- **isotropy**
  - The condition in which the properties are independent of the direction in which they are measured.
- **Izod test**
  - A type of impact test in which a V-notched specimen, mounted vertically, is subjected to a sudden blow delivered by the weight at the end of a pendulum arm. The energy required to break off the free end is a measure of the impact strength or toughness of the material. Contrast with Charpy test .
- **J**
- **jig**
  - A device for both holding a part and guiding the tool during a machining or assembly operation.
- **jiggering**
  - A plastic forming process used with clay-based ceramics in which a plastic mass is pressed under relatively low pressure into a plaster die, and the final shape is achieved by rotating the die and shaping the plastic mass with a fixed tool. Jiggering is a mechanical version of the potter's wheel and produces shapes with circular cross sections such as dinner plates and coffee mugs.
- ***J*-integral**
  - A mathematical expression involving a line or surface integral that encloses the crack front from one crack surface to the other, used to characterize the fracture toughness of a material having appreciable plasticity before fracture. The *J*-integral eliminates the need to describe the behavior of the material near the crack tip by considering the local stress-strain field around the crack front; J_{Ic} is the critical value of the *J*-integral required to initiate growth of a preexisting crack.
- **K**
- **kinematic analysis**
  - An analysis to determine the position, velocity, and acceleration of all bodies in a mechanical system at a sequence of user-specified time steps. This type of analysis is often used to check the range of motion and to determine whether the design will allow motion/velocity/acceleration to be in the expected range.
- **knowledge base**
  - A collection of formulas, rules, and lessons learned that, when connected to a computerized database and manipulated with artificial intelligence methods, allows decisions to be made that approximate those made by humans, but much faster.

- **L**
- **lamina**
  - A single ply or layer in a laminate, which is made up of a series of layers.
- **laminate**
  - A sheet comprised of two or more layers of material (lamina) bonded together. A reinforced laminate usually refers to superimposed layers of resin-impregnated or resin-coated fabrics or fibrous reinforcements that have been bonded, especially by heat and/or pressure.
- **lateral thinking**
  - A thought process in which the mind moves in many different directions, combining different bits of information into new patterns until several different solution concepts evolve. Also called divergent thinking.
- **learning curve**
  - A curve that shows the way that production time or manufacturing cost decreases with cumulative production because of greater worker experience.
- **least commitment policy of design**
  - The concept that it is best to allow as much freedom as possible for downstream decisions in the design process so that engineers are free to develop the best possible solutions unconstrained by previous unnecessary commitments (decisions).
- **life-cycle assessment (LCA)**
  - A "cradle-to-grave" assessment of the energy requirements and environmental impacts of a given product design.
- **life-cycle cost**
  - A cost analysis that considers not only the cost of producing a product, but the cost of using, servicing, and disposing or recycling the product.
- **linear elastic fracture mechanics**
  - A method of fracture analysis that can determine the stress (or load) required to induce fracture instability in a structure containing a crack-like flaw of known size and shape. See also stress-intensity factor .
- **linear programming**
  - A type of optimization algorithm that is very effective for problems where the objective and constraint functions are linear.
- **lockin**
  - A procedure in maintenance that maintains an event or prohibits an individual, an object, force, or other factor from leaving a safe zone.
- **lockout**
  - A procedure in maintenance that prevents an individual, an object, force, or other factor from entering a dangerous zone.
- **low-cycle fatigue**
  - Fatigue that occurs at relatively small numbers of cycles ($<10^4$ cycles). Low-cycle fatigue may be accompanied by some plastic, or permanent, deformation. Compare with high-cycle fatigue .
- **lumped-parameter model**
  - A mathematical model in which the distributed properties of physical quantities are replaced with their lumped equivalents. When a problem can be analyzed in terms of a finite number of discrete elements, it can be expressed by ordinary differential equations. To describe the more realistic case of distributed parameters having many values spread over a field in space requires the use of partial differential equations.
- **M**
- **machinability**
  - The relative ease with which material is removed from a solid by controlled chip-forming in a machining process.
- **magnetically hard alloy**
  - A ferromagnetic alloy capable of being magnetized permanently because of its ability to retain induced magnetization and magnetic poles after removal of externally applied fields; an alloy with high coercive force. The name is based on the fact that the quality of the early permanent magnets was related to their hardness.
- **magnetically soft alloy**

- A ferromagnetic alloy that becomes magnetized readily upon application of a field and that returns to practically a nonmagnetic condition when the field is removed; an alloy with the properties of high magnetic permeability, low coercive force, and low magnetic hysteresis loss.
- **maintainability**
  - In reliability theory, the measure of an item to be retained in, or restored to, a specified condition when maintenance is performed by personnel having specified skill levels and using prescribed procedures and resources, at each prescribed level of maintenance and repair.
- **malleability**
  - The characteristic of metals that permits plastic deformation in compression without fracture. See also ductility .
- **manufacturing**
  - The conversion of materials into finished parts, products, and goods that have value to end-users. Manufacturing involves the design, development, implementation, control, operation, and maintenance of processes that facilitate and perform the conversion of starting materials into finished products having greater value.
- **manufacturing flexibility**
  - The ease with which a process can be adapted to produce different products or variations of the same product. Process flexibility is influenced greatly by the time to set up or change tooling.
- **manufacturing lead time**
  - The time required to process the product through the manufacturing plant. Related to process cycle time.
- **martensite**
  - A generic term for microstructures formed by diffusionless phase transformation in which the parent and product phases have a specific crystallographic relationship. Martensite is characterized by an acicular pattern in the microstructure in both ferrous and nonferrous alloys. In alloys where the solute atoms occupy interstitial positions in the martensitic lattice (such as carbon in iron), the structure is hard and highly strained; but where the solute atoms occupy substitutional positions (such as nickel in iron), the martensite is soft and ductile. The amount of high-temperature phase that transforms to martensite on cooling depends to a large extent on the lower temperature attained, there being a rather distinct beginning temperature (M_s) and a temperature at which the transformation is essentially complete (M_f).
- **mass-conserving process**
  - A manufacturing process in which the mass of the starting material is approximately equal to the mass of the final product or part. Examples are casting, precision forming, and powder processes.
- **mass-reducing process**
  - A manufacturing process in which the mass of the starting material is greater than the mass of the final product or part, and forming takes place by the removal of material, e.g., machining.
- **master product model**
  - An approach toward design in which the product design is centered on an information-rich computer model that supports not only the physical design, but analysis, testing, design, optimization, simulation, prototyping, manufacturing, and maintenance.
- **materials performance index**
  - A combination of materials properties formulated in such a way that the largest value of the index designates the best material for the application. See also performance index .
- **material substitution**
  - A class of material selection problem where a design already exists and the task is to replace the existing material with a more suitable one.
- **material utilization**
  - The percentage of the material processed that ends up in the product. A high material utilization means high product yield and near-net shape processing.
- **mechanism dynamics**
  - The procedure for determining the detailed motions, velocities, and accelerations of the parts in a complex mechanical system. Computer-aided methods, based on the engineering sciences of dynamics and kinematics, are used.
- **melt index**
  - The amount, in grams, of a thermoplastic resin that can be forced through a 2.0955 mm (0.0825 in.) orifice when subjected to 20.7 N (2160 gf) in 10 min at 190 °C (375 °F).
- **melt viscosity**

- The bulk property of a fluid or semifluid (melted) polymer that causes it to resist flow. It is given by the shear stress acting on the fluid divided by the rate of shear. Melt viscosity in polymers is usually measured by the melt index .

- **metadata**
  - Descriptive data about the material for which data are reported. Metadata include a complete description of the material (producer, heat number, grade, temper, etc.), a complete description of the test method, and information about the test plan.
- **metal**
  - An opaque lustrous elemental chemical substance that is a good conductor of heat and electricity and, when polished, a good reflector of light. Most elemental metals are malleable and ductile and are, in general, denser than other elemental substances. As to structure, metals may be distinguished from nonmetals by their atomic binding and electron availability. Metallic atoms tend to lose electrons from the outer shells, the positive ions thus formed being held together by the electron gas produced by the separation. The ability of these "free electrons" to carry an electric current, and the fact that this ability decreases as temperature increases, establish the prime distinctions of a metallic solid.
- **metal injection molding (MIM)**
  - A powder process in which a metal powder is mixed with up to 40% polymer binder and shaped by injection molding. The part is removed from the mold, the binder is removed using either solvent extraction or thermal processes, and the part is sintered to decrease porosity.
- **metal working**
  - See forming .
- **microalloying**
  - A steelmaking technology in which small amounts of alloying elements (vanadium, niobium, or titanium) are used to retard recrystallization of austenite, thereby allowing a wider range of rolling temperatures for controlled rolling. Without retarding recrystallization, as in normal hot rolling, the pancake-type grains do not form and a fine grain size cannot be developed in these ferrite-pearlite steels.
- **microstructure**
  - The structure of an object, organism, or material as revealed by a microscope at magnifications greater than 25.
- **minimum batch size**
  - See break-even analysis.
- **mistake minimization**
  - A process utilized in design to minimize mistakes on system elements for which satisfactory design experience is available. The process involves rigorous application of standards and computerized design methods, reuse of successful designs where possible, and root-cause analysis to eliminate problems from prototypes.
- **model**
  - See process model .
- **modeling**
  - See computer modeling .
- **modulus of elasticity (*E*)**
  - (1) The measure of rigidity or stiffness of a material; the ratio of stress, below the proportional limit, to the corresponding strain. If a tensile stress of 13.8 MPa (2.0 ksi) results in an elongation of 1.0%, the modulus of elasticity is 13.8 MPa (2.0 ksi) divided by 0.01, or 1380 MPa (200 ksi). (2) In terms of the stress-strain curve, the modulus of elasticity is the slope of the stress-strain curve in the range of linear proportionally of stress to strain. Also known as Young's modulus. For materials that do not conform to Hooke's law throughout the elastic range, the slope of either the tangent to the stress-strain curve at the origin or at low stress, the secant drawn from the origin to any specified point on the stress-strain curve, or the chord connecting any two specific points on the stress-strain curve is usually taken to be the modulus of elasticity. In these cases, the modulus is referred to as the tangent modulus, secant modulus, or chord modulus, respectively.
- **modulus of rigidity**
  - See shear modulus .
- **modulus of rupture**

- Nominal stress at fracture in a bend test or torsion test. In bending, modulus of rupture is the bending moment at fracture divided by the section modulus. In torsion, modulus of rupture is the torque at fracture divided by the polar section modulus.

- **moment of inertia**
  - A mathematical quantity used to calculate the stress in bending of beams. The moment of inertia of a plane surface is the sum of the products obtained by multiplying the area of each element of the surface by the square of its distance from the axis.
- **monotonic loading**
  - A testing procedure in which the load on the specimen progressively increases or decreases, but does not oscillate in value.
- **Monte Carlo simulation**
  - A method of generating information for a simulation when events occur in a random way. The Monte Carlo method uses unrestricted random sampling in a computer simulation in which the results are run off repeatedly to develop statistically reliable answers.
- **morphological matrix**
  - In a formalized process for developing design concepts, a list of all functions needed by the design, including all of the conceivable ways of accomplishing each function.
- **morphology**
  - The characteristic shape, form, or surface texture or contours of the crystals, grains, or particles of (or in) a material, generally on a microscopic scale.
- ***m*-value**
  - See strain-rate sensitivity (m-value) .
- **N**
- **natural strain**
  - See true strain .
- **near-net-shape processes**
  - Shape replication processes that produce parts requiring little or no subsequent processing to obtain the finished part.
- **necking**
  - The process by which a material in tension reduces locally its cross-sectional area. Important in creating imperfections and voids in metal deformation processes. A high strain-rate sensitivity in the material means that an incipient neck becomes stronger and spreads the deformation to neighboring material, thereby resisting neck formation.
- **nesting**
  - (1) A condition found when surface finishing or machine assembling small parts where they cluster together, making them difficult to treat as individual parts. (2) Orientation of sheet metal parts so as to minimize waste when cut from a large sheet.
- **net surface**
  - A surface in a manufactured part that requires no finishing in a subsequent operation.
- **Newtonian fluid**
  - A fluid exhibiting Newtonian viscosity wherein the shear stress is proportional to the rate of shear.
- **noise factors**
  - Uncontrollable factors in the design environment that cause quality characteristics to deviate from target values. Noise factors cause variability and quality loss. Robust design corrects for noise factors.
- **normal distribution**
  - The probability density function used to describe the mechanical properties of materials and the distribution of most random variables encountered in engineering design.
- **numerical control programming**
  - The process of developing a set of instructions that controls a machine tool or other manufacturing device to produce a part.
- **O**
- **objective function**
  - In design optimization, the grouping of design parameters that is attempted to be maximized or minimized, subject to the problem constraints. Also known as criterion function.
- **OEM vendors**

- Suppliers of components to original equipment manufacturers (OEM), i.e., those who manufacture and sell the completely assembled product. For example, a typical OEM vendor might provide small electrical motors to the producer of home appliances.
- **operating hazard analysis (OHA)**
  - A hazard analysis that focuses on operating the product, including testing, maintaining, repairing, transporting, and handling. Emphasis is on people performing tasks. Note that FMEA, FTA, and FHA deal primarily with problems of hardware.
- **optimization**
  - The process of searching for the best combination of design parameters. Design optimization suggests that for a given set of possible designs and design criteria there exists a single design that is best or optimal.
- **orange peel**
  - (1) In metals, a surface roughening in the form of a pebble-grained pattern that occurs when a metal of unusually coarse grain size is stressed beyond its elastic limits. (2) In injection molding of plastics, a part with an undesirable uneven surface somewhat resembling the skin of an orange. (3) In ceramics, a pitted texture of a fired glaze resembling the surface of a rough orange peel.
- **orthogonal array**
  - A balanced fractional factorial type of design of experiments. Used as a key part of robust design to determine the effect each factor has on the mean and the variability in an experiment where many factors are involved.
- **overhead costs**
  - Any cost not directly associated with the production of identifiable goods or services. Sometimes called burden or indirect costs.
- **oxidation reaction**
  - In electrochemistry, a chemical reaction that occurs at an anodic site by the liberation of electrons.
- **oxidation resistance**
  - Ability of a material to resist degradation by reacting with air or another gas to form a surface oxide.
- **oxide-dispersion-strengthened (ODS) alloys**
  - A class of materials in which fine oxide particles are incorporated in metal powders, compacted, and then fabricated into finished forms by deformation processing. The resulting material has improved thermal softening resistance with excellent thermal and electrical conductivity. Examples are ODS copper alloys and sintered aluminum powder (SAP).
- **P**
- **parameter design**
  - The second stage of the robust design process, as defined by Genichi Taguchi, in which a robust design is achieved by optimizing performance of the system through experimentation that minimizes variation in the presence of uncontrolled user and environmental factors (noise).
- **parametric design**
  - The third stage of the engineering design process, usually called detail design . In this stage of design, detailed analysis determines the final shape, dimensions, and properties of parts. Optimization methods, especially those employed in robust design are used to enhance quality. Final decisions are made on materials and manufacturing processes, and the part cost is determined.
- **parison**
  - The hollow plastic tube from which a plastic component is blow molded.
- **part**
  - Designed object that has no assembly operations in its manufacture. Parts may be either standard or special purpose. A standard part, like a screw or spring, has a generic function and is manufactured in quantity without the intention of being used in a particular product. A special-purpose part is designed and manufactured for a specific purpose in a specific product.
- **particle strengthening**
  - A common form of strengthening in metals, in which small second-phase particles are distributed in a ductile matrix. Examples are precipitation-hardening (age-hardening) systems and dispersion-hardened alloys.
- **parts list**
  - See bill of materials .

- **patent**
  - A grant made by a government to an inventor that permits him or her the sole right to make, sell, and use the invention for a period of time.
- **PDES/STEP**
  - A standard data protocol for the transfer of digital data between different software and machines. PDES is more comprehensive than the Initial Graphics Exchange Standard (IGES) in that it includes product attributes such as material type and form features in addition to solid model topology.
- **performance index**
  - Groupings of material properties that when maximized optimizes some aspect of performance; for example, $\sigma_f/E\alpha$ leads to improved thermal shock resistance. See also materials performance index .
- **performance standards**
  - Standards that state design requirements but not the methods that are to be used to achieve the objective.
- **permeability**
  - A general term used to express various relationships between magnetic induction and magnetizing force. These relationships are either "absolute permeability," which is a change in magnetic induction divided by the corresponding change in magnetizing force, or "specific (relative) permeability," the ratio of the absolute permeability to the permeability of free space.
- **pH**
  - The negative logarithm of the hydrogen-ion activity; it denotes the degree of acidity or basicity of a solution. At 25 °C (77 °F), 7.0 is the neutral value. Decreasing values below 7.0 indicates increasing acidity; increasing values above 7.0, increasing basicity. The pH values range from 0 to 14.
- **phase**
  - A physically homogeneous and distinct portion of a material system.
- **phase diagram**
  - A graphical representation of the temperature and composition limits of phase fields in an alloy or ceramic system as they actually exist under the specific conditions of heating or cooling. A phase diagram may be an equilibrium diagram, or a representation of metastable conditions or phases. Synonymous with constitution diagram.
- **plastic**
  - A material that contains as an essential ingredient an organic polymer of large molecular weight; is solid in its finished state; and, at some stage in its manufacture or its processing into finished articles, can be shaped by flow. Although materials such as rubber, textiles, adhesives, and paint may in some cases meet this definition, they are not considered plastics. The terms plastic, resin, and polymer are somewhat synonymous, but the terms resins and polymers most often denote the basic material as polymerized, while the term plastic encompasses compounds containing plasticizers, stabilizers, fillers, and other additives.
- **plastic deformation**
  - The permanent (inelastic) distortion of materials under applied stresses that strain the material beyond its elastic limit.
- **plasticity**
  - The property of a material that allows it to be repeatedly deformed without rupture when acted upon by a force sufficient to cause deformation and that allows it to retain its shape after the applied force has been removed.
- **plastic strain ratio (*r*-value)**
  - In formability testing of metals, the ratio of the true width strain to the true thickness strain in a sheet tensile test, $r = \varepsilon_w/\varepsilon_t$. A formability parameter that relates to drawing, it is also known as the anisotropy factor. A high *r*-value indicates a material with good drawing properties.
- **Poisson's ratio (*v*)**
  - The absolute value of the ratio of transverse (lateral) strain to the corresponding axial strain resulting from uniformly distributed axial stress below the proportional limit of the material.
- **polar moment of inertia**
  - The moment of inertia where the distance is measured from an axis perpendicular to the plane of the area.
- **polymer**

    - A high-molecular-weight organic compound, natural or synthetic, with a structure that can be represented by a repeated small unit, the mer. Examples include polyethylene, rubber, and cellulose. Synthetic polymers are formed by addition or condensation polymerization of monomers. Some polymers are elastomers, some are plastics, and some are fibers. When two or more dissimilar monomers are involved, the product is called a copolymer. The chain lengths of commercial thermoplastics vary from ~1000 to >100,000 repeating units. Thermosetting polymers approach infinity after curing, their resin precursors, often called prepolymers, may be relatively short--6 to 100 repeating units--before curing. The lengths of polymer chains, usually measured by molecular weight, have very significant effects on the performance properties of plastics and profound effects on processibility.
- **polymer blend**
    - A mixture of different types of polymer chains. In miscible blends the polymers mix on a molecular level to produce a single phase, as in the blend of polyphenylene oxide and polystyrene. In immiscible blends the polymers cannot mix on a molecular level and separate into two phases, as in blends of ABS and polystyrene.
- **polymer casting**
    - To form a "plastic" object by pouring a fluid monomer-polymer solution into an open mold where it finishes polymerizing. Forming plastic film and sheet by pouring the liquid resin onto a moving belt or by precipitation in a chemical bath.
- **population**
    - A statistical concept describing the total set of objects or observations under consideration.
- **porosity**
    - Fine holes or pores within a solid; the amount of these pores is expressed as a percentage of the total volume of the solid.
- **powder forging (P/F)**
    - The plastic deformation of a powder metallurgy compact or preform into a fully dense finished shape by using compressive force; usually done hot and within closed dies.
- **powder metallurgy (P/M)**
    - The technology and art of producing metal powders and utilizing metal powders for production of mass materials and shaped objects.
- **precipitation hardening**
    - Hardening in metals caused by the precipitation of a constituent from a supersaturated solid solution.
- **precision**
    - In testing, a measure of the variability that can be expected among test results. The precision of an instrument indicates its ability to reproduce a certain reading. Precision is the inverse of standard deviation. A decrease in the scatter of test results is represented by a smaller standard deviation, leading directly to an increase in precision.
- **preimpregnation**
    - (reinforced plastics). The practice of mixing resin and reinforcement and effecting partial cure before use or shipment to the user. See also prepreg .
- **prepreg**
    - In composites fabrication, either ready-to-mold material in sheet form or ready-to-wind material in roving form, which may be cloth, mat, unidirectional fiber, or paper, impregnated with resin and stored for use. The resin is partially cured to a B-stage and supplied to the fabricator, who lays up the finished shape and completes the cure with heat and pressure. The two distinct types of prepreg available are commercial prepregs, in which the roving is coated with a hot melt or solvent system to produce a specific product to meet specific customer requirements; and wet prepreg, in which the basic resin is installed without solvents or preservatives but has limited room-temperature shelf life.
- **prescriptive standard**
    - A standard that states the requirements in terms of specific details and leaves no discretion to the designer. Sometimes referred to as a design standard.
- **probability density function (PDF)**
    - A mathematical function that, when integrated between two limits, gives the probability that a random variable assumes a value between these limits.
- **process capability**
    - A statistical measure of the inherent process variability with respect to some characteristic.

- **process-driven design**
    - A design approach in which the manufacturing process plan or method of assembly is developed prior to developing the product design.
- **process model**
    - A mathematical description of the physical behavior underlying a manufacturing process that is used to predict performance of the process in terms of operating parameters. Most often process models are reduced to software and are manipulated with computers.
- **product design specification (PDS)**
    - See engineering design specification .
- **product documentation**
    - All of the documentation, whether on paper or in digital form, that defines the steps in designing the product and the specifies the steps required for its manufacture. These include: product design specification, QFD matrices, concept selection results, geometric dimensioning and tolerancing schemes, detail drawings, bill of materials , and manufacturing process plans.
- **product integrity**
    - In the manufacturing sense, it is the absence of voids, pores, cracks, and harmful inclusions.
- **products liability**
    - A legal term that describes the action whereby an injured party (plaintiff) seeks to recover damages for personal injuries or property loss from a producer and/or seller (defendant) when the plaintiff alleges that a defective product or design caused the injury or loss.
- **property of unique interest**
    - A material property that is of such importance or uniqueness to the application that this single property predominates all other considerations in materials selection.
- **prototype**
    - A full-scale working model of the design that is technically and visually complete. See also rapid prototyping .
- **Pugh concept selection method**
    - See concept selection method .
- **Q**
- **quality**
    - The characteristics of a product or service that bear on its ability to satisfy stated or implied needs. A quality product or service is free from deficiencies.
- **quality assurance**
    - All the planned and systematic activities implemented within a quality system that provide confidence that a product or service will deliver the required quality.
- **quality control**
    - The operational techniques and activities used to fulfill the requirements for quality. Often quality assurance and quality control are used interchangeably.
- **quality function deployment (QFD)**
    - A product planning tool that uses a matrix to map the customer wants to the quantified specifications of the design (product). Often called the house of quality (because of the house-shaped QFD matrices). The QFD approach that is used at the first stage of product planning can be deployed all the way down the stage of production planning on the shop floor.
- **quality loss function**
    - An approach to evaluating quality, introduced by Genichi Taguchi, in which quality is measured by the dollar loss due to some quality characteristic deviating from the target value. Mathematically, the loss function is a quadratic function of the deviation from the target value.
- **quench cracking**
    - Fracture of a metal during quenching from elevated temperature. Most frequently observed in hardened carbon steel, alloy steel, or tool steel parts of high hardness and low toughness. Cracks often emanate from fillets, holes, corners, or other stress raisers and result from high stresses due to the volume changes accompanying transformation to martensite.
- **R**
- **random variable**
    - A parameter or variable that deviates from some measure of average performance or central tendency in a predictable way.
- **rapid prototyping**

- A process by which a design created by computer solid modeling can be created quickly as a physical object or assembly that can be used for visualization and functional testing.
- **rationalization**
  - See standardization and rationalization .
- ***R*-curve**
  - In fracture mechanics, a plot of crack-extension resistance as a function of stable crack extension, which is the difference between either the physical crack size or the effective crack size and the original crack size. *R*-curves normally depend on specimen thickness and, for some materials, on temperature and strain rate.
- **readiness review**
  - A final review of an engineered system from the viewpoint of readiness for safe operation. All critical personnel are brought together and all safety hazards are reexamined to see whether the hazards have been adequately addressed. Operating procedures are assessed to ensure that personnel are properly trained, not only for normal operation, but also for emergency situations.
- **recycling**
  - The reassimilation of a material into the raw materials stream in a matter such that it may be used for a purpose identical or similar to that of its first use. A material must be recovered or reclaimed from a waste stream before it is available for recycling. Recycling is different from reuse or remanufacture .
- **redesign**
  - The process of redoing an existing design to improve some deficiency in the existing design.
- **reduction in area (RA)**
  - The difference between the original cross-sectional area of a tensile specimen and the smallest area at or after fracture as specified for the material undergoing testing. Also known as reduction of area.
- **reduction reaction**
  - In electrochemistry, a chemical reaction taking place at cathodic sites by the consumption of electrons.
- **reentrant angle**
  - An interior angle of a polygon greater than 180°.
- **refractory**
  - A material (usually an inorganic, nonmetallic, ceramic material) of very high melting point with properties that make it suitable for such uses as furnace linings and kiln construction.
- **reliability**
  - A measure of the capacity of equipment or a system to operate without failure in the service environment. Reliability is always expressed as a probability of performing for a given time without failure.
- **remanufacture**
  - A form of green design in which parts and components are rebuilt or refurbished after a portion of their life so that they may be reissued and used as essentially new parts.
- **repair**
  - Corrective action made on a damaged product so that the product will fulfill the original specifications.
- **requirements list**
  - See engineering design specification .
- **residual stress**
  - A stress that exists in a solid body without an imposed external force. Residual stresses often result from forming or thermal processing and are caused by such factors as cold working, phase changes, temperature gradients, or rapid cooling.
- **resin**
  - A solid, semisolid, or pseudosolid organic material that has an indefinite and often high molecular weight, exhibits a tendency to flow when subjected to stress, usually has a softening or melting range, and usually fracture conchoidally. (2) In reinforced plastics, the material used to bind together the reinforcement material; the matrix.
- **resistivity**
  - See electrical resistivity .
- **response surface modeling**

- A statistical, mathematical, or graphical model that describes the variation of the response variable in terms of the parameters of the problem.
- **retained austenite**
  - An amount of the high-temperature face-centered cubic phase of iron (austenite) that does not transform to martensite (is retained) when quenched to room temperature.
- **reverse engineering**
  - The process of determining design concepts or details by disassembling a similar or competitive product.
- **rework**
  - An action taken on nonconforming products or services to allow them to meet the original specifications.
- **rheology**
  - The science of deformation and the flow of matter.
- **risk**
  - The probability of damage or injury. The potential for harm to people, property, or the environment.
- **risk/benefit analysis**
  - A decision-making technique that uses a common value scale, usually dollars, to balance the risk against benefit.
- **robust design**
  - An integrated system of tools and techniques that are aimed at reducing product or process performance variability while simultaneously guiding that performance toward an optimal setting. Robustness optimization is chiefly done for design concepts that are new so that the best values of the critical functional parameters are unknown. Robust design follows the methods first proposed by Genichi Taguchi.
- **robustness**
  - Performance of a system that is always acceptably close to the ideal function of the system. It refers to how consistently a component or product performs under variable conditions in its environment and as it wears during its lifetime.
- **rotational casting**
  - A method used to make hollow articles from thermoplastic materials. The material is charged into a hollow mold capable of being rotated in one or two planes. The hot mold fuses the material into a gel after the rotation has caused it to cover all surfaces. The mold is then chilled, and the product is stripped out.
- **rotational molding**
  - The preferred term for a variation of the rotational casting process that uses dry, finely divided (35 mesh, or 500 μ) plastic powders, such as polyethylene, rather than fluid materials. After the powders are heated, they are fused against the mold walls forming a hollow item with uniform wall thickness.
- **rules of thumb**
  - Empirical relationships developed from practical experience. In design, often used to improve ease of manufacture or to relate performance to costs. Rules of thumb can be very useful when employed by an experienced person, but they may easily be misinterpreted or misused by less experienced personnel.
- ***r*-value**
  - See plastic strain ratio (r-value) .
- ***R*-value**
  - In fatigue testing, the stress ratio determined by the minimum stress in the stress cycle divided by the maximum stress. For a completely reversed stress cycle, R = -1.
- **S**
- **safety factor**
  - See factor of safety .
- **sales point**
  - A feature of a product that gives it a competitive advantage. This term is used in the quality function deployment methodology.
- **sample**
  - In statistics, part of a population that is withdrawn for study or observation. The most important type of sample is a random sample, which is defined as a collection of objects from a population

selected in such a way that each item in the population has the same likelihood of being a member of the sample. Other types of samples are stratified or biased samples.

- **sandwich construction**
  - A panel composed of a lightweight core material, such as honeycomb, cellular or foamed plastic, and so forth, to which two relatively thin, dense, high-strength or high-stiffness faces, or skins, are adhered.
- **scanning electron microscope (SEM)**
  - A high-power magnifying and imaging instrument using an accelerated electron beam as an optical device and containing circuitry which causes the beam to traverse or scan an area of sample in the same manner as does an oscilloscope or TV tube. May utilize reflected or transmitted electron optics. The scanning electron microscope provides two outstanding improvements over the optical microscope; it extends the resolution limits so that picture magnifications can be increased from 1000 to 2000× up to 30,000 to 60,000×, and it improves the depth-of-field resolution more dramatically, by a factor of approximately 300, thus facilitating its use in fracture studies.
- **screening property**
  - Any material property for which an absolute lower (or upper) limit can be established in the material selection process. These are often referred to as go/no-go limits.
- **secondary manufacturing operation**
  - A manufacturing operation used to impart close tolerances or controlled surface finish to a part. Machining operations are a good example.
- **sensitivity analysis**
  - An analytical method for determining the importance of each design parameter to the performance of the design (output measure) and the critical ranges of those parameters.
- **sequential engineering**
  - An older style of product development in which design decisions are made in a rigid linear pattern, e.g., all decisions on functionality are made before any decisions of production method, etc. This is being supplanted by concurrent engineering .
- **shape design parameter**
  - A design parameter that describes the boundary position in a numerical (FEM) model, and thus defines nodal location. Optimizing a shape design parameter may require that the entire finite element model be remeshed.
- **shape generation process**
  - A mass-reducing process in which the shape of the part is determined by the pattern of relative motion between the cutting tool and the part. Shape information is impressed by the process.
- **shape memory alloy (SMA)**
  - A type of metallic material that demonstrates the ability to return to some previously defined shape or size when subjected to the appropriate thermal treatment. These materials can be plastically deformed at some relatively low temperature and, upon exposure to some higher temperature, will return to their shape prior to the deformation. Commercially promising systems are alloys of Ni-Ti, Cu-Zn-Al, and Cu-Al-Ni.
- **shape replication process**
  - A mass-conserving process in which the part replicates the shape information stored in the die or mold by being forced to assume the shape of the surface of the tool cavity.
- **shear modulus (*G*)**
  - The ratio of shear stress to the corresponding shear strain for shear stresses below the proportional limit of the material. Values of shear modulus are usually determined by torsion testing. Also known as modulus of rigidity.
- **sheet forming**
  - The plastic deformation of a piece of sheet metal by tensile loads into a three-dimensional shape, often without significant changes in sheet thickness or surface characteristics. Compare with bulk forming .
- **shelf energy**
  - In the Charpy impact test, shelf energy is the upper (plateau) value of energy absorbed at a temperature well above the ductile-to-brittle transition temperature.
- **shot peening**
  - A method of cold working metals in which compressive stresses are induced in the exposed surface layers of parts by impingement of a stream of shot (small spherical particles), directed at

the metal surface at high velocity under controlled conditions. It differs from blast cleaning in primary purpose and in the extent to which it is controlled to yield accurate and reproducible results. Although shot peening cleans the surface being peened, this function is incidental. The major purpose of shot peening is to increase fatigue strength. Shot for peening is made of iron, steel, or glass.

- **shrinkage**
  - A common manufacturing term that denotes changes in a dimension on cooling from temperature, e.g., in forgings, castings, or molded plastics. Shrinkage in castings can result in internal voids.
- **signal-to-noise ratio**
  - A transformation of the data of an experimental design that indicates how much variation around the mean is shown by the data. Large values represent more robust behavior.
- **simulation**
  - The representation of a real system by a set of models, usually mathematical or computer based, and subjecting these models to various inputs or environmental conditions to assess how the real system might behave.
- **simultaneous engineering**
  - See concurrent engineering .
- **sintering**
  - The bonding of adjacent surfaces of particles in a mass of powder or a compact by heating. Sintering strengthens a powder mass and normally produces densification and, in powdered metals, recrystallization.
- **size effect**
  - The behavior in which the dimensions of the test specimen affect the value of the mechanical property measured. Most prominent for fatigue properties and strength of brittle materials, where strength is lower for large section size.
- **sizing design parameter**
  - A design parameter that does not alter the location of nodes in a numerical (FEM) model of the design. Examples are material properties and boundary conditions.
- **slip casting**
  - The ceramic forming process consisting of filling or coating a porous mold with a slip, allowing to dry, and removing for subsequent firing.
- **slip system**
  - The combination of slip plane with the close-packed slip directions that lie in the plane.
- **social costs**
  - The costs of a product that are borne by society at large. An example is the cost of emissions resulting from extraction, processing, using, and disposing of a material or product.
- **solid modeling**
  - A form of computer modeling in which the three-dimensional features of the part or object are represented. With solid modeling, a cut through the model reveals interior details. The method also permits accurate calculation of mass properties (e.g., mass and moment of inertia), and, with full color, shading, and shadowing, it creates realistic displays. Solid models may be integrated with motion analysis software to create realistic simulations. Solid models may also be linked with finite element models.
- **soldering**
  - A group of processes that join metals by heating them to a suitable temperature below the solidus of the base metals and applying a filler metal having a liquidus not exceeding 450 °C (840 °F). Molten filler metal is distributed between the closely fitted surfaces of the joint by capillary action.
- **solvation**
  - The process of swelling, gelling, or dissolving a resin by a solvent or plasticizer.
- **spallation**
  - The cracking or rupturing of a solid body, which usually results in the detachment of a portion of the solid.
- **special-purpose part**
  - Parts that are designed and manufactured especially for use in a particular product.
- **specification**
  - A detailed statement describing the materials, dimensions, manufacturing process. See engineering design specification .

- **specific modulus**
  - The material elastic modulus divided by the material density.
- **specific strength**
  - The material strength divided by the material density.
- **spinoidal hardening**
  - Strengthening caused by the formation of a periodic array of coherent face-centered cubic solid-solution phases on a submicrostructural size level.
- **spray drying**
  - A powder-producing process in which a slurry of liquids and solids or a solution is atomized into droplets in a chamber through which heated gases, usually air, are passed. The liquids are evaporated from the droplets, and the solids are collected continuously from the chamber. The resulting powder consists of free-flowing, spherical agglomerates.
- **springback**
  - (1) The elastic recovery of metal after stressing. (2) The extent to which metal tends to return to its original shape or contour after undergoing a forming operation. This is compensated for by overbending or by a secondary operation of restriking.
- **standard deviation**
  - A measure of the dispersion of observed values or results from the average expressed as the positive square root of the variance.
- **standardization**
  - (1) The process of establishing, by common agreement, engineering criteria, terms, principles, practices, materials, items, processes, and equipment parts and components. (2) The adoption of generally accepted uniform procedures, dimensions, materials, or parts that directly affect the design of a product or a facility.
- **standardization and rationalization**
  - A combined design and business approach that specifically targets reduction in the number of parts company-wide. Standardization refers to the reduction in number of parts used in current and former designs. Rationalization is the identification of the fewest number of parts required for use in future designs.
- **standard module**
  - A product manufactured in quantity for use in a number of other products. Examples are motors, clutches, switches, pumps, etc. Standard modules are usually offered for sale through the catalogs of their manufacturers.
- **standard part**
  - See part .
- **standard time**
  - Time required to perform a step in a manufacturing or assembly operation of a product. These times, usually in seconds, are obtained from empirical observations.
- **stochastic search methods**
  - A large group of optimization techniques that utilizes probabilistic methods. Two common methods are genetic algorithms and simulated annealing.
- **stoichiometric**
  - Having the precise weight relation of the elements in a chemical compound; or (quantities of reacting elements or compounds) being in the same weight relation as the theoretical combining weight of the elements involved.
- **strain**
  - The unit of change in the size or shape of a body due to force. Also known as normal strain. The term is also used in a broader sense to denote a dimensionless number that characterizes the change in dimensions of an object during a deformation or flow process.
- **strain hardening**
  - An increase in hardness and strength of metals caused by plastic deformation at temperatures below the recrystallization range. Also known as work hardening.
- **strain-rate sensitivity (*m*-value)**
  - The increase in stress (σ) needed to cause a certain increase in plastic strain rate ($\dot{\varepsilon}$) at a given level of plastic strain (ε) and a given temperature (T):

$$\text{Strain-rate sensitivity} = m = \left(\frac{\Delta \log \sigma}{\Delta \log \dot{\varepsilon}}\right)_{\varepsilon T}$$

- **stress**
  - The intensity of the internally distributed forces or components of forces that resist a change in the volume or shape of a material that is or has been subjected to external forces. Stress is expressed in force per unit area. Stress can be normal (tension or compression) or shear.
- **stress concentration**
  - On a macromechanical level, the magnification of the level of an applied stress in the region of a notch, void, hole, or inclusion.
- **stress concentration factor (K_t)**
  - A multiplying factor for applied stress that allows for the presence of a structural discontinuity such as a notch or hole, K_t equals the ratio of the greatest stress in the region of the discontinuity to the nominal stress for the entire section. Also called theoretical stress concentration factor.
- **stress-intensity factor**
  - A scaling factor, usually denoted by the symbol *K*, used in linear-elastic fracture mechanics to describe the intensification of applied stress at the tip of a crack of known size and shape. At the onset of rapid crack propagation in any structure containing a crack, the factor is called the critical stress-intensity factor, or the fracture toughness. Various subscripts are used to denote different loading conditions or fracture toughnesses:

K_c	Plane-stress fracture toughness. The value of stress intensity at which crack propagation becomes rapid in sections thinner than those in which plane-strain conditions prevail.
K_I	Stress-intensity factor for a loading condition that displaces the crack faces in a direction normal to the crack plane (also known as the opening mode of deformation).
K_{Ic}	Plane-strain fracture toughness. The minimum value of K_c for any given material and condition, which is attained when rapid crack propagation in the opening mode is governed by plane-strain conditions.
K_{Id}	Dynamic fracture toughness. The fracture toughness determined under dynamic loading conditions; it is used as an approximation of K_{Ic} for very tough materials.
K_{ISCC}	Threshold stress intensity factor for stress-corrosion cracking. The critical plane-strain stress intensity at the onset of stress-corrosion cracking under specified conditions.
K_Q	Provisional value for plane-strain fracture toughness.
ΔK	The range of stress-intensity factor during a fatigue cycle.

- **stress relaxation**
  - The time-dependent decrease in stress in a solid under constant constraint at constant temperature.
- **stress relief**
  - The removal or reduction of residual stress by thermal treatment, mechanical treatment (shot peening, surface rolling, stretching, bending, and straightening), or vibratory stress relief.
- **stress-strain curve**
  - A graph in which corresponding values of stress and strain from a tension, compression, or torsion test are plotted against each other. Values of stress are usually plotted vertically (ordinates or *y*-axis) and values of strain horizontally (abscissas or *x*-axis). Also known as deformation curve and stress-strain diagram.
- **stretch forming**
  - The forming of a sheet material by the penetration of a sheet into a blank clamped firmly at its circumference. Deformation occurs chiefly by reducing thickness and increasing surface area.
- **structure-insensitive properties**

    - Material properties that are determined more by the composition of the material than by its structure. Examples are density, elastic modulus, and thermal conductivity.
- **structure-sensitive properties**
    - Material properties that are strongly dependent on microstructural features and defect structure. Examples are yield strength and fracture toughness.
- **subassembly**
    - An assembly that is included within another assembly or subassembly. See also assembly .
- **subcritical crack growth (SCG)**
    - A failure process in which a crack initiates at a preexisting flaw and grows until it attains a critical length. At that point the crack grows in an unstable fashion leading to catastrophic failure. Typical examples of SCG processes are fatigue failure and stress corrosion.
- **suboptimization**
    - The optimization of a part of a large, complex engineering system with many parameters. Suboptimization of all subparts of a large system does not in general lead to optimization of the whole system. Suboptimization is successful in improving quality only when the subsystems are loosely coupled.
- **superplasticity**
    - The ability of certain metals (most notably aluminum- and titanium-base alloys) to develop extremely high tensile elongations under controlled rates of deformation at elevated temperatures.
- **surface engineering**
    - Treatment of the surface and near-surface regions of a material to allow the surface to perform functions that are distinct from those functions demanded from the bulk material. Examples are case hardening or galvanizing of a steel surface.
- **surface finish**
    - (1) The geometric irregularities in the surface of a solid material. Measurement of surface finish shall not include inherent structural irregularities unless these are the characteristics being measured. (2) Condition of a surface as a result of a final treatment.
- **surface finishing**
    - The process of applying a surface treatment to clean the surface, to improve its appearance, or to give it a special property such as corrosion or wear resistance.
- **surface hardening**
    - A localized heat treating process that produces a hard-quenched surface in steel without introducing additional alloying elements. Surface hardening can be produced by flame, induction, or laser or electron beam thermal treatments.
- **surface integrity**
    - A technology that involves the specification and manufacture of unimpaired or enhanced surfaces through the control of the many possible alterations produced in a surface layer during manufacture. Surface integrity is achieved by the proper selection and control of manufacturing processes and the ability to estimate their effects on the significant engineering properties of work materials.
- **surface topography**
    - The fine-scale features of a surface as defined by the size and distribution of asperities. Surface topography is measured by surface roughness and the direction of surface features (lay).
- **synectics**
    - A creative problem-solving process in which the problem statement or product design specification is transformed through the use of analogies.
- **system architecture**
    - The total plan for the design or product that lays out the type of subsystems and ensures that they are properly related. A complex system would contain the following levels: total system, module, subsystem, subassembly, piece part, and piece-part feature.
- **system design**
    - The primary product-development stage in which the basic architecture of the product or process is determined. The first stage of robust design , as defined by Genichi Taguchi.
- **system verification test**
    - A final verification of robustness of the system that is usually performed on the first total-system prototypes, which are made after the detail design has been completed.
- **T**

- **tack**
  - The ability of a material (usually a polymer) to stick to itself and to other materials. A tacky material will stay in place when positioned in a mold or on top of another layer of material.
- **Taguchi methods**
  - See robust design .
- **taxonomy**
  - The principles and process of classification.
- **temper**
  - In nonferrous alloys and in some ferrous alloys (steels that cannot be hardened by heat treatment), the hardness and strength produced by mechanical or thermal treatment, or both, and characterized by a certain structure, mechanical properties, or reduction in area during cold working.
- **tempering**
  - (1) In heat treatment, reheating hardened steel to some temperature below the eutectoid temperature to decrease hardness and/or increase toughness. (2) The process of rapidly cooling glass from near its softening point to induce compressive stresses on the surface balanced by interior tension, thereby imparting increased strength.
- **tensile strength**
  - In tensile testing, the ratio of maximum load to original cross-sectional area. Also called ultimate strength. Compare with yield strength .
- **texture**
  - In a polycrystalline aggregate, the state of distribution of crystal orientations. In the usual sense, it is synonymous with preferred orientation, in which the distribution is not random.
- **thermal barrier coating (TBC)**
  - A thick (125-250 μm) insulating layer, designed to reduce the temperature at the metal interface. A plasma sprayed layer of yttria-stabilized zirconia is frequently used.
- **thermal conductivity**
  - (1) Ability of a material to conduct heat. (2) The rate of heat flow, under steady conditions, through unit area, per unit temperature gradient in the direction perpendicular to the area. Usually expressed in English units as Btu per square feet per degrees Fahrenheit ($Btu/ft^2 \cdot °F$). It is given in SI units as watts per meter Kelvin ($W/m \cdot K$).
- **thermal fatigue**
  - Fracture resulting from the presence of temperature gradients that vary with time in such a manner as to produce cyclic stresses in a structure.
- **thermoforming**
  - The process of forming a thermoplastic sheet into a three-dimensional shape after heating it to the point at which it is soft and flowable, and then applying differential pressure to make the sheet conform to the shape of the mold or die.
- **thermomechanical working**
  - A general term covering a variety of metal forming processes combining controlled thermal and deformation treatments to obtain synergistic effects, such as improvement in strength without loss of toughness. Same as thermal-mechanical treatment.
- **thermoplastic**
  - Capable of being repeatedly softened by an increase in temperature and hardened by a decrease in temperature. Those polymeric materials that, when heated, undergo a substantially physical rather than chemical change and that in the softened stage can be shaped into articles by molding or extrusion.
- **thermoset**
  - A resin that is cured, set, or hardened, usually by heating, into a permanent shape. The polymerization reaction is an irreversible reaction known as cross linking. Once set, a thermosetting plastic cannot be remelted, although most soften with the application of heat.
- **thixotropy**
  - A property of certain gels or slurry mixtures to thin upon stirring agitation (shearing) and to thicken upon subsequent rest.
- **throw-away product**
  - Small, inexpensive products that are designed without any consideration of repair.
- **time-temperature-transformation (TTT) diagram**
  - See isothermal transformation (IT) diagram.

- **tolerance**
  - The total amount by which a specific dimension may be allowed to vary without impairing performance. The tolerance is the difference between the allowable limits.
- **tolerance analysis**
  - See dimensional management .
- **tolerance design**
  - The third stage of robust design , as defined by Genichi Taguchi, in which it is decided how much performance levels of certain parameters will have to be increased to meet the quality characteristic. The quality loss function is used to find the most cost-effective way of determining which tolerances will have to be tightened and which can be left as is or opened up, in order to reduce cost.
- **tolerance stackup**
  - The situation with a subassembly of several parts by which all parts are within the tolerance specification, but the cumulative effect of the tolerance of each part results in a critical dimension of the assembly being out-of-tolerance.
- **topology optimization**
  - Design optimization carried out early in configuration design that computes the best geometric configuration or layout of a structure.
- **torsion**
  - The state of stress produced by applying torque to a bar or shaft.
- **total quality management (TQM)**
  - A management approach to long-term success that emphasizes customer satisfaction. The elements of TQM are continuous improvement, involving all members of the organization, and decision making based on data, using a set of simple TQM analysis tools.
- **toughness**
  - Ability of a material to absorb energy and deform plastically before fracturing. Toughness is proportional to the area under the stress-strain curve from the origin to the breaking point. In metals, toughness is usually measured by the energy absorbed in a notch impact test.
- **tow**
  - An untwisted bundle of continuous filaments, usually referring to man-made fibers, particularly carbon and graphite, but also fiberglass and aramid. A tow designated as 140 K has 140,000 filaments.
- **trade-off**
  - A situation commonly found in design where more than one functional characteristic of the design is of value to the user. Often it is found that these characteristics oppose one another, and a compromise must be achieved. For example, with many materials, increasing the strength reduces fracture toughness, and a trade-off must be reached. Trade-off studies are best done after gathering data from a sensitivity analysis .
- **transformation-induced plasticity (TRIP)**
  - A phenomenon, occurring chiefly in certain highly alloyed steels that have been heat treated to produce metastable austenite or metastable austenite plus martensite, whereby, on subsequent deformation, part of the austenite undergoes strain-induced transformation to martensite. Steels capable of transforming in this manner, commonly referred to as TRIP steels, are highly plastic after heat treatment, but exhibit a very high rate of strain hardening and thus have high tensile and yield strengths after plastic deformation at temperatures between 20 and 500 °C (70 and 930 °F). Cooling to -195 °C (-320 °F) may or may not be required to complete the transformation to martensite. Tempering usually is done following transformation.
- **transformation temperature**
  - The temperature at which a change in phase occurs. This term is sometimes used to denote the limiting temperature of a transformation range.
- **transition temperature**
  - (1) An arbitrarily defined temperature that lies within the temperature range in which metal fracture characteristics (as usually determined by tests of notched specimens) change rapidly, such as the ductile-to-brittle transition temperature (DBTT). The DBTT can be assessed in several ways, the most common being the temperature for 50% ductile and 50% brittle fracture (50% fracture appearance transition temperature, or FATT), or the lowest temperature at which the fracture is 100% ductile (100% fibrous criterion). The DBTT is commonly associated with temper embrittlement and radiation damage (neutron irradiation) of low-alloy steels. (2)

Sometimes used to denote an arbitrarily defined temperature within a range in which the ductility changes rapidly with temperature.

- **true strain**
    - (1) The ratio of the change in dimension, resulting from a given load increment, to the magnitude of the dimension immediately prior to applying the load increment. (2) In a body subjected to axial force, the natural logarithm of the ratio of the gage length at the moment of observation to the original gage length. Also known as natural strain.
- **true stress**
    - The value obtained by dividing the load applied to a member at a given instant by the cross-sectional area over which it acts.
- **U**
- **ultimate strength**
    - See tensile strength .
- **uncertainty**
    - The condition of being in doubt. In statistical terms it refers to the bounds within which the "true" engineering result, such as the average fatigue limit of a component, can be expected to fall. Generally described in terms of confidence limits, tolerance limits, or prediction limits.
- **undercut**
    - In welding, a groove melted into the base metal adjacent to the root of the weld and left unfilled by weld metal.
- **undercut shape**
    - A shape in which material has been removed to create an overhang.
- **V**
- **validation**
    - The process of substantiating that material property test data have been generated according to standard methods and practices, or other indices of quality, reliability, and precision. The validation process is the first step toward ratification or confirmation of the data, making them legally effective and binding in some specified application.
- **value**
    - The worth of a product or service, equal to function divided by cost or quality divided by cost.
- **value analysis**
    - A problem-solving methodology that focuses on identifying the key function(s) of a design so that unnecessary costs can be removed without compromising the quality of the design. Also known as value engineering.
- **value engineering**
    - See value analysis .
- **variability of data**
    - The degree to which random variables deviate from a central value or mean. In statistical terms, this is measured by the sample standard deviation or sample variance.
- **variable costs**
    - Those costs that can be directly associated with the production of a unit of output, and whose total increases roughly linearly with the total number of units produced. A good example of variable costs is material costs. See also fixed costs .
- **vertical thinking**
    - A thought process that moves forward in sequential steps after a positive decision has been made about the idea.
- **virtual manufacturer**
    - A company that focuses on the design and marketing of a product and outsources the manufacturing and assembly of the product to other companies.
- **viscoelasticity**
    - A property involving a combination of elastic and viscous behavior that makes deformation dependent upon both temperature and strain rate. A material having this property is considered to combine the features of a perfectly elastic solid and a perfect fluid.
- **vitrification**
    - The formation of a glassy phase in a ceramic body that serves to bind the particulate material together and close the pores.
- **W**
- **weakest-link failure theory**

    - A concept of failure in which failure is caused by the weakest element in a body, as in the failure of the weakest link in a chain.
- **wear**
    - Damage to a solid surface, generally involving progressive loss of material, due to a relative motion between that surface and a contacting surface or substance.
- **wear rate**
    - The rate of material removal or dimensional change due to wear per unit of exposure parameter--for example, quantity of material removed (mass, volume, thickness) in unit distance of sliding or unit time.
- **Weibull distribution**
    - The probability density function commonly used to describe the strength of brittle materials such as ceramics and glasses. Also used to describe the fatigue performance of complex assemblies.
- **weighted property index**
    - An index that uses weighted values of the required properties to arrive at a relative value for selection of a material for a specific application.
- **weldability**
    - A specific or relative measure of the ability of a material to be welded under a given set of conditions. Implicit in this definition is the ability of the completed weldment to fulfill all functions for which the part was designed.
- **weld-overlay coatings**
    - Surface coatings applied for corrosion, wear, or erosion resistance by melting and solidifying a molten alloy produced by a welding process. Sometimes referred to as hardfacing.
- **welding**
    - Joining two or more pieces of material by applying heat or pressure, or both, with or without filler material, to produce a localized union through fusion or recrystallization across the interface. The thickness of the filler material is much greater than the capillary dimensions encountered in brazing .
- **whiteware**
    - A group of ceramic products characterized by a white or light-colored body with a fine-grained structure that consist primarily of clay materials, feldspars, and quartz. Most whiteware products are glazed--in whole or in part--and whiteware glazes may range from clear to completely opaque, white or colored. Examples of whiteware products are sanitaryware, tableware, electrical porcelain, artware, stoneware, and tile.
- **workability**
    - See formability .
- **work hardening**
    - See strain hardening .
- **Y**
- **yield strength**
    - The stress at which a material exhibits a specified deviation from proportionality of stress and strain. An offset of 0.2% is used for many materials, particularly metals. Compare with tensile strength .
- **Young's modulus**
    - See modulus of elasticity (*E*) .

Abbreviations and Symbols

- o **Abbreviations and Symbols**
- ***a***
    - crack length; thermal diffusivity of a product
- **A**
    - ampere
- ***A***
    - area; ratio of the alternating stress amplitude to the mean stress
- Å
    - angstrom

- **ABC**
  - activity-based costing
- **ac**
  - alternating current
- **AI**
  - artificial intelligence

- ***X***
  - neck diameter
- ***Y***
  - scale of microstructural segregation
- **YAG**
  - yttrium aluminum garnet
- **yr**
  - year
- ***z***
  - ion charge
- ***Z***
  - atomic number; impedance
- **°**
  - angular measure; degree
- **°C**

- degree Celsius (centigrade)
- **°F**
  - degree Fahrenheit
- **0°**
  - fiber direction
- **90°**
  - perpendicular to fiber direction
- α
  - coefficient of thermal expansion
- γ
  - shear strain; surface energy; surface tension
- $\gamma_{\mathbf{b}}$
  - interfacial energy
- $\gamma_{\mathbf{s}}$
  - surface energy
- δ
  - an increment; a range; change in quantity; grain boundary width; thickness of liquid boundary
- Δ
  - an increment; a range; change in quantity
- ΔT
  - temperature difference or change
- ε
  - strain
- $\dot{\varepsilon}$
  - strain rate
- η
  - loss coefficient; viscosity
- θ
  - angle; geometrical constant
- $\theta_{\mathbf{i}}$
  - angle of incidence
- $\theta_{\mathbf{r}}$
  - angle of refraction
- κ
  - dielectric constant
- λ
  - thermal conductivity
- μ
  - friction coefficient; linear attenuation coefficient; magnetic permeability; the mean (or average) of a distribution
- μ**in.**
  - microinch
- μ**m**
  - micrometer (micron)
- μ**s**
  - microsecond
- ν
  - Poisson's ratio; velocity
- π
  - pi (3.141592)
- ρ
  - density; resistivity
- σ
  - Stefan-Boltzmann constant; strength; stress; tensile stress; tensile strength
- $\sigma_{\mathbf{a}}$
  - applied stress
- $\sigma_{\mathbf{f}}$
  - applied axial load
- Σ

- summation of
- τ
  - shear stress
- ϕ
  - angle of internal friction; dihedral angle; porosity; power
- Φ
  - reaction rate (kinetic function); volume concentration of impurity ions
- ψ
  - damping; geometrical constant
- ω
  - frequency
- Ω
  - atomic volume; electrical conductivity; molecular volume of solute; ohm
- ∂
  - partial derivative
- $\partial\eta/\partial t$
  - kinetic function
- $\leftrightarrows$
  - direction of reaction
- ÷
  - divided by
- =
  - equals
- $\approx$
  - approximately equals
- $\neq$
  - not equal to
- $\equiv$
  - identical with
- >
  - greater than
- $\gg$
  - much greater than
- $\geq$
  - greater than or equal to
- ∞
  - infinity
- $\propto$
  - is proportional to; varies as
- $\int$
  - integral of
- <
  - less than
- $\ll$
  - much less than
- $\leq$
  - less than or equal to
- ±
  - maximum deviation
- -
  - minus; negative ion charge
- ×
  - diameters (magnification); multiplied by
- ·
  - multiplied by
- /
  - per
- %
  - percent

- +
  - plus; positive ion charge
- $\sqrt{}$
  - square root of
- $\sim$
  - approximately; similar to

- **Greek Alphabet**
- **A,** α
  - alpha
- **B,** β
  - beta
- Γ, γ
  - gamma
- Δ, δ
  - delta
- **E,** ϵ
  - epsilon
- **Z,** ζ
  - zeta
- **H,** η
  - eta
- Θ, θ
  - theta
- **I,** ι
  - iota
- **K,** κ
  - kappa
- Λ, λ
  - lambda
- **M,** μ
  - mu
- **N,** ν
  - nu
- Ξ, ξ
  - xi
- **O, o**
  - omicron
- Π, π
  - pi
- **P,** ρ
  - rho
- Σ, σ
  - sigma
- **T,** τ
  - tau
- Υ, υ
  - upsilon
- Φ, ϕ
  - phi
- **X,** χ
  - chi
- Ψ, ψ
  - psi
- Ω, ω

- omega
